	Wool Blacks (Ber)	110,244
217	Agalma Black 10BX	40,763
	Naphthol Blue Blacks (C)	62,864
220	Palatine Blacks	148,203
272	Brilliant Blacks (B)	39,454

(3) Specialties for Lakes.

Many of the dyestuffs used for this purpose are included in their respective lists. Certain acid dyestuffs adapted to this purpose only are given below It will be noted that Red is by far the most important color, with importations of 987,715 lbs.

		Pounds
	Claret Lake BL (By)	15,290
	Helio Bordeaux BL (By)	14,703
	Hansa Rubine G O (M)	6,000
152	Permanent Red 4B	44,850
	Permanent Red B R 4R (Ber)	56,545
132	Lake Red P (M)	60,345
153	Lake Red C Extra (M)	306,607
45	Brilliant Lake Red R (M)	31,674
173	Lithol Red R (B)	214,448
	Lithol Reds various (B)	67,515
73	Helio Fast Red RL (By)	13,413
	Lithol Fast Scarlets (B)	36,295
	Paratol Scarlet 3B (M)	41,000
56	Autol Red BL paste (B)	49,847
	Red Lake RL (By)	9,686
	Lithol Fast Orange R (B)	36,641
	Quercitron Substitute V WBL (B)	16,812
	Paratol Chrome Yellow L (M)	17,336
	Hansa Yellows (M)	11,014
4	Naphthol Green B	19,146
	Lake Blues (M)	8,887
	Pigment Blacks (B)	22,448

As the following intermediates are chiefly used for lakes the importations are given below. Intermediates, i. e., b-naphthol, p-nitraniline, used both for lakes and in dyeing are given later.

	Pounds
m.—Nitro—p. toluidine	10,513
o.— “ —“— “	20,737
p.— “ —o.— “	30,642

(4) Vat Colors.

Up to this point the colors enumerated are principally used for Wool; the classifications which follow refer, generally speaking, to Cotton colors. The figures in this group refer to a business which as regards Indigo is a development of the last fifteen years and of not much more than half this period in the case of the other colors. It is interesting to note that Blue predominates in this group to the extent of 93%. Even with Indigo excluded the proportion is 62%. The total importations are 10,322,683 lbs., or excluding Indigo 1,815,324 lbs.

In *Red* the importations were 148,526 lbs. The most important colors are:

		Pounds
827	Indanthrene Claret B Extra (B)	28,728
918	Helindone Red 3B	27,874
831	Indanthrene Red BN Extra (B)	6.056
910	Helindone Pink AN BN	39,393
907	Ciba Scarlet G 20%	22,265
916	Helindone Scarlet S	5,515

In *Orange* the importations were 94,938 lbs. The most important colors are:

		Pounds
761	Indanthrene Golden Orange R (B)	50,496
760	“ “ “ G (B)	20,092
913	Helindone Orange R	14,489
822	Algol Brilliant Orange FR (By)	6,195

In *Yellow* the importations were 115,838 lbs. The most important colors are:

		Pounds
849	Indanthrene Yellow G (B)	75,192
810	Helindone Yellows CG RN (M)	20,744
759	Anthraflavone G (B)	7.143
814	Algol Yellow WF (By)	5,185
817	Algol Yellow R (By)	4,887

In *Green*, excluding Indanthrene Green B, which is largely used for black, the importations total only 19,180 lbs. The most important color is:

		Pounds
833	Algol Olive R (By)	13,334

In *Blue* the importations total 9,645,821. lbs. Excluding Indigo the various Indanthrene Blues account for 728,194 lbs. out of a total of 1,138,462 lbs. The most important colors are:

		Pounds
874	Indigo	8,507,359
888	“ G	10,730
879	“ R	53,610
880	“ RB	6,856
886	Brilliant Indigo G (B)	12,057
885	“ “ B (B)	8,175
881	Ciba Blue 2B	16,880
748	Hydrone Blues (C)	292,729
842	Indanthrene Blue GCD (B)	478,980
841	“ “ 2GS (B)	10,163
	“ “ WR (B)	31,658
838	“ “ RS (B)	187,379
763	“ Dark Blue BO (B)	11.096
839	Algol Blue 3G (By)	5,994

In *Violet* the importations total 153,738 lbs. The most important colors are:

		Pounds
767	Indanthrene Violet 2R Extra (B)	68,419
832	“ “ RN “ (B)	11 667
820	Algol Brilliant Violet R (By)	12,784
901	Ciba Violet B (I)	19,830
920	Helindone Violet B 2B R	28,607

In *Brown* the importations are only 23,831 lbs The important colors are:

		Pounds
867	Indanthrene Brown B (B)	6.175
904	Helindone Brown G	12,936

In Grey and Black the importations total 130,811 lbs. The important colors are:

		Pounds
834	Algol Grey B 2B (By)	4,192
765	Indanthrene Black B 2B (B)	122,261

(5) Sulphur Colors.

In this group *Black* predominates to the extent of 80% in importations totaling 7,072,676 lbs. The range of shades is incomplete for lack of Red and Orange in clear tones.

In *Yellow* the importations total 111,390 lbs. The most important colors are:

		Pounds
710	Immedial Yellows (C)	13,395
734	Pyrogene Yellows M O (I)	18,515
	Katigene Yellow G 2G GR (By)	55,227
	Thiogene Yellow 2G 5G (M)	5,545

In *Green* the importations total 115,356 lbs., inclusive of 14,398 lbs. of Olive. The most important colors are:

		Pounds
	Immedial Brilliant Green G (C)	4,799
746	Katigene Greens	63,929
	Sulphur Greens (Ber)	9,157
	Thiogene Greens (M)	8,106
	Immedial Yellow Olives (C)	8,293

In *Blue* the importations total 462,053 lbs, the Immedial group with importations of 208,694 lbs. predominating. The most important colors are:

		Pounds
	Immedial New Blue G (C)	37,492
	“ Direct Blue (C)	73,892
	“ Indogenes (C)	90,077
	Sulphur Indigoes (Ber)	10,488

722	Auronal Blacks (G)	50,879
	Crossdye Blacks (RH)	38,583
	Sulphur Blacks (Lev)	33,892

(6) Developed Colors.

Supplementing and serving a similar purpose to the Sulphur colors, these dyestuffs were imported to the extent of 1,644,272 lbs. In addition to these, imports of Formaldehyde colors were 11,444 lbs. and Nitrazol developed colors only 7,986 lbs. As with the Sulphur group Black predominates to the extent of 83% of the total.

In *Red* the importations total 163,083 lbs. The most important colors are:

		Pounds
	Zambesi Rubine B	18,617
	Diazo Bordeaux 7B (By)	7,670
	“ Fast Bordeaux BL (By)	3,194
	“ Brilliant Scarlets (By)	38,909

	Diamine Azo Scarlets (C)	6,646
	Diazanil Scarlets (M)	4,125
616	Primuline	67,976

In *Blue* the importations total 79,523 lbs. The most important colors are:

	Pounds
Naphthogene Blues (Ber)	33,847
Oxamine Fast Blues 2R 6BX (B)	8,435
Diaminogene Blues (C)	8,308
Diamine Azo Blues (C)	3,497
Diaminogene Sky Blue N (C)	3,195
Diazo Sky Blue B 3GL (By)	6,150
“ Indigo Blues (By)	7,484

In *Brown* the importations are only 9.162 lbs The important colors are:

	Pounds
Diazo Browns (By)	5,134
Zambesi Browns (Ber)	4,028

In *Black* the importations total 1,369,065 lbs., excluding Diamine Black BH, which is given with the Direct colors. The most important colors are:

		Pounds
	Zambesi Blacks (Ber)	629,359
274	Diaminogenes (C)	305,944
	Oxydiaminogenes (C)	139,118
	Diamine Neron BB (C)	36,982
308	Diazo Blacks (By)	62,854
	“ Fast Blacks (By)	29,330
	Oxamine Blacks BB RN A BRTX (B)	50,032
	Naphthamine Fast Blacks (K)	34,203

(7) Direct Colors.

In order that their significance may be better grasped an attempt has been made to separate the direct colors claiming special fastness to light from the ordinary direct colors. Of the former the importations were 843,083 lbs., of the latter 6,129,801 lbs.

In *Red* the importations total 75,665 lbs. for fast-to-light colors and 912,121 lbs. for the ordinary colors. The most important are:

		Pounds
	Benzo Fast Bordeaux 6BL (By)	6,056

	Benzo Fast Yellow 4GL RL (By)	6,535
615	Thioflavine S	4,948
394	Chrysamine R	6,261

In *Green* there is no fast-to-light direct color Importations total 250,978 lbs. In this group the variations in shade and properties are small. 221.708 lbs. of this amount represents products similar to or identical with Diamine Green The most important colors are:

		Pounds
474	Diamine Greens (C)	53,268
	Direct Green (Gr)	31,194
474	Oxamine Greens (B)	31,161
478	Columbia Greens (Ber)	24,749
	Diphenyl Greens (G)	18,021
	Benzo Greens (By)	16,506
	" Dark Greens	23,414

In *Blue* the imports of the fast-to-light brands were 104,944 lbs. out of a total of 1,048,824 lbs., to which should be added 699,588 lbs. Diamine Black BH, etc., which is probably most extensively used as a navy blue. Reference has already been made to the 79,523 lbs. of Developed Blue imported. The most important colors are:

		Pounds
	Brilliant Fast Blues (By)	11,513
456	Benzo Fast Blue B BN	73,936
	" " " 2GL 4GL, etc. (By)	26,559
	" " " R (By)	4,449
	Diamine Fast Blues (C)	28,880
	Columbia Fast Blue 2G R Extra (Ber.)	84,661

In *Violet* the importations were 390,080 lbs. The most important colors are:

		Pounds
518	Ethyl Purple	51,933
516	Crystal Violet	74,259
515	Methyl Violet	255,063
	Methylene Violets, etc	9,825

In *Brown* the importations were 275,194 lbs. The most important colors were:

		Pounds
283/4	Bismarck Brown	206,153
	Kraft Browns (B) (mixtures)	55,042
	Havana Browns “	8,594

In *Black* the importations were 98,989 lbs. The most important colors are:

		Pounds
681	New Fast Grey	29,507
125	Diazine Black	2,630
	Leather Black (mixtures)	34,561
	Corvoline BT (B) “	10,789
	Jet Black “	21,492

(9) Sundries.

Of Oil colors the importations were relatively small, the largest being Oil Orange, 12,000 lbs., and Oil Blacks, $50,000 lbs.

(10) Intermediates.

The most important of those used for dyeing purposes are given below, but the figures also include the amounts used by domestic dyestuff manufacturers before the war.

		Pounds
923	Ursol	52,720
	p—phenylene Diamine	14,616
	m— “ “	37,907
	m—toluylene “	33,355

	Naphthol AS	1,997
	Monosulphonic Acid	32,852
	p—nitraniline	506,931
	a—naphthylamine	112,226
	Aniline Oil	1,444,772
	“ Salts	3,083,467

Exportation of Domestic Aniline Colors

Notwithstanding the constantly increasing demands of the domestic market and the handicap caused by munition manufacturers drawing more and more largely on the available supply of toluol and other coal-tar derivatives vitually essential as raw material for the dyestuff industry, exports of aniline colors during September show a gain over the preceding month of $66,800, or 21.9 per cent., according to a statement issued recently by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce. September exports by customs districts indicate that $261,454, or over two-thirds the total value of all aniline colors shipped abroad, passed through New York; $47,913 through the Massachusetts district, $6,515 through West Coast districts, $1,630 across our Mexican border, and the remainder through districts adjacent to Canada.

The total exportation of aniline colors for the first quarter of the current fiscal year amounted to $1,173,439, of which $497,106 worth was shipped in July, distributed among 21 foreign countries; $304,768 in August to 21 countries; and $371,565 in September to 17 countries—or an average monthly exportation of $391,146 for the first quarter in which aniline dyes are shown separately in the statistical classification.

England is our best customer so far, having taken $195,195 of the aniline colors exported during the quarter ending September 30, 1917, followed by British India, with $184,967; Canada, $161,581; Spain, $105,504; France, $86,379; Japan, $80,073; Mexico, $75,353; Italy, $67,484, and other countries with less extensive purchases.

It is worthy of note that the United States is the only country which has succeeded in establishing, since the war began, a successful dyestuff industry capable

(*Concluded on page* 64)

Prospective Nitroglycerine Plant.

The French-Agnew Torpedo Company, Zanesville, Ohio, is considering the erection of a large plant for the manufacture of nitroglycerine at Winchester, Kentucky.

$8,000 Fire at Bine Brothers'.

Fire recently destroyed a portion of the plant of Bine Brothers, Cook's Falls, New York, with loss estimated at about $8,000. The company specializes in the production of sulphur colors.

Dyestuffs, Explosives and Coal-Tar Products.

The Delta Chemical Company, Inc., Manhattan, has been incorporated under the laws of New York to manufacture chemicals, dyestuffs, explosives and coal-tar products. H. Wilkinson, M. Thyvaert and C. Gander are the incorporators of the new firm, which has an active capital of $5,000 and 100 shares of common stock, no par value.

Oils, Greases, Tars, and Chemicals.

The United Ohio and Chemical Corporation has been incorporated under the laws of Delaware with a capital of $2,000,000 by F. A. Armstrong, C. M. Egner and W. S. Randall, Wilmington, Delaware, to deal in and with oils, greases, tars and chemicals.

Alkali and Chemicals.

The Western Alkali Refining Co., Wilmington, Del., has been incorporated with a capital of $2,000,000 to make alkali and chemicals. The incorporators are C. R. Mudge, C. D. Hopkins and A. M. Gorman, Wilmington.

FOREIGN TRADE OPPORTUNITIES

(See Also Page 77)

General Chemicals.

25781.—A company in Japan who has recently opened a branch office in the United States desires to secure agencies for the sale of machinery, metals, chemicals, electrical motors, etc. Business will be done on a commission basis, or direct purchases will be made. References.

Aniline Colors and Dyestuffs.

25790.—A firm in Italy desires to purchase aniline colors and dyestuffs for cotton and woolen goods. Quotations should be cabled with estimate on freight rates to Genoa. Cash will be paid. Correspondence may be in English.

Chemical Products and Dyestuffs.

25783.—A society in France is in the market for chemical products, pure or for industrial use; dyestuffs and extracts; and pharmaceutical products. Correspondence may be in English. Usual terms are 30 days. References.

Equipment for Small Tannery.

25761.—A firm in Venezuela is in the market for complete equipment for a small tannery. Quotations should be made f. o. b. New York. Payment will be made by cash against documents in New York. Correspondence may be in English. References.

Dyes and Equipment for Woolens.

25551.—A man in Canada desires to purchase dyes and dyers' equipment suitable for dyeing woolen goods. Cash will be paid.

Dyes, Bleaches, Etc.

25643.—An agency is desired by a firm in France for the sale of chemical products, dyestuffs, and all supplies relative to the bleaching, dyeing, printing, and finishing of tissues. Correspondence should be in French. Reference.

Dry Paint, Drugs and Chemicals.

25622.—The representative of a firm in Canada wishes to be placed in communication with American manufacturers and exporters of dry paints, drugs, and chemicals, with a view to securing agencies for the sale of same. All business is desired on a commisssion basis. References.

Explosives for Mining.

25433.—A mining company in Tunisia wishes to communicate with manufacturers of all kinds of mining machinery, including explosives, tools, mine drills, ventilators, mine railways, ore washers, electric motors, machine tools, lubricants, transmissions, steel cables, etc. Correspondence must be in French. References.

The Inspection and Testing of Trinitro-Toluene

(Concluded from page 55)

exposed mercury stem as follows: while the thermometer is registering approximately the melting point, place a drop of melted diphenylamine on the stem and allow to flow down. For a small distance above the water surface the diphenylamine will remain molten: above this it will solidify. Note the point separating the solid from the melted diphenylamine.

Then, if N = No. of degrees of mercury stem exposed above this point.

Ta = Surrounding air temperature and Tm = Melting Point the correction is, $N(Tm - Ta) \times 0.000154$.

Add this correction to the recorded temperature (*b*) for the corrected M. P.

The grading of the TNT being almost entirely dependent upon this determination, the method should be carefully followed.

Comment—The tubes above mentioned seem too large in diameter, and a tube 1 mm. or less in diameter would give a result closer to the real melting point.

One-quarter inch of substance is sufficient, because the higher the column, the more difficult it is to decide when half is melted completely, since this compound does not always melt in one place in the tube, but often at the top and bottom simultaneously, and it is left to the operator's judgment at which point the reading is to be taken.

The three readings are usually taken as a check on each other.

Solidifying Point.

The uncertainty of the M. P. is avoided to a great degree, when the solidifying point is determined. Only one set of specifications gives the method which is described by E. M. Weaver, Brig. General U. S. A. and Chief of Coast Artillery, in his book "Notes on Military Explosives."

METHOD—Place 200 to 250 g. TNT in a dry porcelain dish of 15 cm. diameter and 500 cc. capacity. Melt below 90° C., remove heat and stir with thermometer. The temperature falls gradually until the TNT begins to crystallize, when it rises. Continue stirring until the highest temperature is reached: this is the solidifying point.

Comment—This determination is more apt to give consistent results, and is simple enough so that different operators usually check each other closely.

It is more accurate, since a larger sample is used, and the point of taking the reading more certain than in the M. P. determination.

The above method is followed, without adhering to the size or form of dish. The majority of chemists use smaller dishes, test tubes and beakers without varying results.

Although the M. P. and S. P. are generally considered the same, there is some difference, reports from different chemists showing the S. P. to be in some instances higher and in others lower than the M. P. Some report identical results for the two.

The writer has noted that where the M. P. was higher than the TNT had been dried at 50° C., and where lower, the undried sample had been used. Further evidence is necessary for a decision on this point.

STABILITY TESTS are not usually required on crude material, although some specifications have required it on refined, as follows:

The substance, about 3 g., is placed in a 6-in. test tube having a strip of potassium iodide starch paper suspended on a glass hook which passes through the stopper. The tube with contents is placed in a bath and heated to 65° C. for from 15 to 30 minutes (depending on specification). No blue color showing presence of nitrous acid should develop. This is known as the "Abel" heat test and is usually used on less stable nitro compounds.

Carnegie Institute of Technology, Pittsburgh, Pa.

Exportation of Domestic Aniline Colors

(Concluded from page 61)

of meeting not only the color requirements of its domestic manufacturers of textiles, paper, paints, and pigments, leather, straw, inks, stains, varnishes, waxes, etc., but of exporting considerable quantities to our allies and neutral countries.

Using the quarterly figures as a basis for the estimate, we are now exporting our surplus production of aniline colors at the rate of $4,693,756 annually, or practically twice the value of our entire domestic production for the fiscal year 1914, which amounted to $2,470,096. This refers to values only, which are, of course, much higher comparatively at the present time.

These figures of production and exportation apply to the coal-tar dyes only, and take no account of our equally well developed trade in logwood extract, osage orange, and other vegetable colors.

British Imports of Dyestuffs.

The statistics for the imports of dyeing materials into Great Britain during the month of July 1917, show notable increases in value, as compared with July, 1916, accompanied, however, in some cases, by decreases in quantity. The following are the important items, figures for 1916 being appended in parenthesis:

Cutch	179 long tons	(371)
Dyeing extracts	$567,000	($346,000)
Indigo	41.2 tons	(32.1)
Value	$229,500	($141,600)
Other dyestuffs, including coal-tar colors	672 tons	(1,025)
Value	$952,000	($726,000)

CHEMICAL INVESTIGATION
EFFICIENCY & CONTROL

CONDUCTED BY CHARLES B. DAVIS, F.C.S.

ALL classes of work covered by the following subjects will be done for readers of "The Chemical Engineer" through this department by Mr. Davis: Special research of every description; analysis and reproduction of any commercial product; prevention of waste and utilization of by-products on the most economical basis; valuation of raw materials; food analysis, and disputed points in regard to adulteration, labeling, and the enforcement of pure food laws; bacteriological and enzymatic examinations, including fermentation tests, pure yeast cultures, beverages of all kinds; development of chemical inventions and industrial processes; examinations and advice on special machinery.

Inquiries of a minor character will be answered on this page, while major matters involving personal investigations, analyses, etc., will, if desired, be treated confidentially through the mails. All questions, materials for analysis, or letters leading to the opening of negotiations for special work will receive prompt attention if addressed to

CHARLES B. DAVIS,
Care of "The Chemical Engineer," 118 East 28th Street,
New York City.

A. S. T.—The sample of clay submitted to me by you for complete chemical analysis and identification has been finished with the results below tabulated:

SiO_2	44.82
Fe_2O_3	25.85
Ae_2O_3	2.63
CaO	7.51
MgO	1.97
K_2O	2.52
Loss on ignition	14.70
	100.00

Have also made a rational analysis of your sample, and report the following fractions:

Clay substance*	66.01
Quartz	32.52
Feldspar	1.47
	100.00

Note.—The texture and grain of this refractory material suit it best for fireclay.

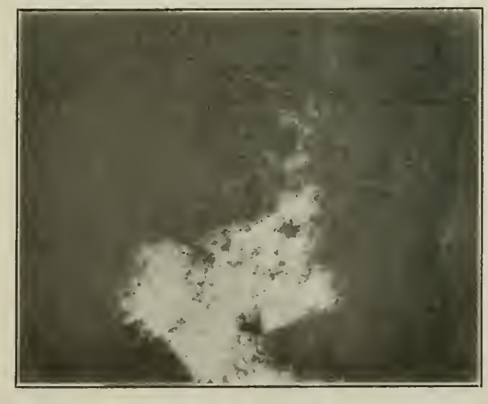
A. W. A.—A kernel of corn is a humble but potent unit. The crop last year amounted to 2,583,241,000 bushels. Of this 40,000,000 was consumed in the manufacture of corn starch, corn syrup and grape sugar.

The following quantities of materials can be produced from one bushel of corn:

1.50 lbs. corn oil.
1.75 lbs. corn oilcake.
10.50 lbs. gluten feed.
1.25 lbs. steep water solids.
41.00 lbs. corn syrup of 41 Beaume, or
41.00 lbs. grape sugar, or
40.00 lbs. dry starch, or
3.00 gal. of 180 proof spirit.

I would suggest that you send me samples from each shipment to test as to moisture, gluten, starch and ash content.

S. S. T.—Syrup such as you describe is manufactured from malt and corn starch. The enzyms Diastase and Hemicellutase are caused to act on the starch and cellulose to produce considerable maltose sugar and some dextrine. These products are used considerably in medicine. The temperatures used can be given you if you so desire. See microphotograph.



D. J. B.—Brewers' yeast, if properly treated to remove the bitter hop principles, may be used for baking by adding an equal weight of distillers' yeast, and prolonging the doughing period.

Hundreds of tons of this yeast from breweries are at present thrown away, but could be used with profit if a process could be devised to purify it.

There is a process at present for converting it into a product quite similar to beef extract.

Charles B Davis

Those whose inquiries to this department have not as yet received attention must bear in mind that unless replies by mail are specifically requested, communications can only be considered in the order of their receipt.—Editor.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By Carleton Ellis and A. A. Wells.[*]

In This, the Ninth Installment of an Article Dealing with Investigations Conducted by the Writers Into the Possible Applications of Ultra Violet Light, the Relative Sterilizing Action of Its Rays Is Discussed, Together With Its Effects on Diphtheria Toxin, Various Enzymes; Its Behavior Toward Wines, Flour, Starch, Artificial Dyes; Its Use in the Vulcanization of Rubber and as an Illuminant in Photography. Part X Will Appear in the January Issue.

PART IX

Relative Sterilizing Action of Ultra Violet Rays.

Cernovodeanu and *Henri* (Comptes. rend. 1910, 150, 549) have compared the photochemical action of various chemical reactions such as: Decomposition of hydrogen peroxide, decomposition of potassium iodide in presence of hydrochloric acid and in presence of starch, reaction between mercuric chloride and ammonium oxalate, oxidation of leuco-derivatives of fluorescein, and the blackening of silver citrate paper. Taking as a standard the action of the rays passing through a glass screen of one millimeter in thickness (wave length over 3022 Angstrom units), the rays passing through a viscous screen having a wave length of over 2534 units, were found to have 300 times the bactericidal power but only 1.6 to 5 times the chemical action, and rays passing through a quartz screen, with a wave length over 2224 units, had only 4-6 times the chemical action, while the sterilizing power had increased to 1,000 times the standard. The germicidal action is therefore a much more characteristic property of the ultra violet rays than the photochemical action. Living organisms are never subjected in nature to ultra violet rays with a wave length under 2800-2900 units, this being the limit of the ultra violet rays reaching the earth from the sun. A Cooper Hewitt mercury lamp of 110 volts and 3 amperes was used for these experiments.

Ozone and Water Formation.

Weigert and *Böhm* (Z. physik. Chem. *90*, 189; Chem. Abs. 1915, 3013) have made a quantitative investigation of the catalytic influence of ultra violet rays on the simultaneously occurring ozone decomposition and the water formation. The experimental method which permits the action of ultra violet rays from a quartz lamp to act on mixtures of hydrogen and ozonized oxygen in variable proportions, is described. The radiations had to pass through so long a layer of gas that, even with small ozone concentration, all the effective light was absorbed. By the measurement of the volume change of the illuminated gas, and by chemical analysis of the gas both before and after radiation, the extent of the participation of the water formation and the ozone decomposition in the photochemical process has been ascertained. It has been found that in the dark no appreciable reaction between hydrogen and ozone takes place within an hour. During radiation the following processes occur simultaneously: (1) $2\ O_3 = 3\ O_2$ and (2) $H_2 + O_3 = H_2O + O_2$. The formation of hydrogen peroxide has not been observed. From a graphical consideration of the change in volume which occurs when the contents of the reaction vessel are subjected to radiation, it is found that with a large excess of hydrogen the contraction associated with water formation occurs, while with large ozone excess the dilation associated with ozone decomposition takes place. At the transition point, out of every three oxygen molecules, two decompose in accordance with equation (1) and one in accordance with equation (2). The photochemical decomposition of ozone is a relatively slower process in the presence of hydrogen. It is however, greatly accelerated by the presence of small quantities of hydrogen but then within a large ozone interval proceeds proportionately to the ozone concentration and above 8% of hydrogen is independent of the hydrogen concentration. From the deviations of the curves from a straight line at the beginning and the end, it has been calculated that the "order" of the ozone decomposition is greater than one in experiments with a large hydrogen excess, and less than one in experiments with a large oxygen excess. It has been shown that the effect of two simultaneously occurring photochemical reactions cannot be regarded as the sum of the effects of the individual processes. In the presence of smaller ozone concentrations, the photochemical water formation proceeds proportionately to those concentrations but approximates a limiting value at higher ozone concentrations, this value being higher the greater the partial pressure of the hydrogen. With constant ozone concentration the water formation is approximately proportional to the hydrogen concentration. With about 100-fold hydrogen excess over the quantity which is necessary for the formation of water in accordance with equation (2), only this reaction takes place.

Effects of Different Wave Lengths.

According to Kowalski-Wierusz (U. S. patent 1,207,347; J.S.C.I. 1917, 90) distinction must be made between three different zones of ultra violet rays, corresponding to the effects which the rays produce. The first zone, or the initial ultra violet, extends from the visible spectrum to about a wave-length of 3,000 Angstrom units. The radiation which corresponds to the rays of this zone is abundantly emitted by the sun. It is but slightly absorbed by the atmosphere. The photochemical reactions which this radiation produces are exothermic almost without exception. The physiological and biological properties are similar to those of the adjacent blue and violet radiation, but more intense. This radiation exerts almost no destructive action on the lower forms of life, such as bacteria. The second zone comprises the so-called middle ultra violet; and extends from about 3,000 to 2,000 Angstrom units. Only the first part of this zone is found in sunlight. The rays of this zone are strongly absorbed by many substances, and therefore the photochemical effects of this radiation are very intense. There is known a whole series of endothermic chemical reactions which are prolonged at the expense of this radiation. Biologically they are bactericidal and coagulate albumin. Finally, the third zone, the extreme ultra violet, corresponds to wave lengths of about 2,000 to 1,000 Angstrom units. This zone can hardly be technically considered at the present time, because radiation of this kind is completely absorbed by a few centimeters of air.

---

[*] All rights of publication in book form reserved by the authors Consulting Chemists and Chemical Engineers, 92-98 Greenwood Ave., Montclair, N. J.

The middle ultra violet rays may be produced by means of the spark gap, and these radiations between 2,900 and 2,200 Angstrom units are effective for sterilization purposes for the following reasons: The investigations of Henri have shown that the shorter the wave length, the more intense is the bactericidal action of the radiations and other investigations have shown that the calcium ion strongly absorbs the short wave lengths. In consequence of this, rays of less than 2,200 Angstrom units are not to be considered in the sterilization of drinking water, which contains more or less calcium.

The method of Kowalski-Wierusz consists in employing a considerable damping of the spark gap, as high a current amplitude as possible, and a wave length of less than 3,000 meters for the oscillation creating the sparks. The damping is obtained by the use of a material for the electrodes which emits ultra violet rays in this sphere. Nickel, cobalt, and alloys of these two metals may be used with other metals and especially with the metals of the rare earths. Moreover, zirconium, tungsten and molybdenum may be employed when the discharge takes place in an inert gas such as hydrogen or nitrogen; a jet of gas may also be injected into the spark gap to increase the spark decrement.

By experiment, it has been shown that the number of spectral lights is not only dependent on the capacity and self-induction used but also on all the electrical conditions of the oscillating circuit and, as regards the radiant energy of different parts of the ultra violet being influenced in a different manner by suitable conditions of the circuit. A series of tests demonstrated that with the increase of the maximum amplitude of current in the oscillation circuit the zone which corresponds to the maximum of radiant energy is displaced toward the shorter wave lengths.

In spark gaps, in which the so-called spark damping is greater, the wave length which corresponds to the maximum of radiant energy is shorter than for spark gaps with less damping. This result can be taken as indicating that the maximum radiation of energy is displaced toward short wave lengths if much energy is consumed in the spark gap. With different electrodes the position of the maximum of radiant energy in the spark was dependent upon the electrode material and is different with an alloy of two metals than with the pure metals, the spark damping being greater with certain alloys, as for example, invar, than with the pure metals. In order to obtain a favorable efficiency of radiation in the middle ultra violet, as great as possible amplitude of current must first be obtained in the oscillation. This, however, is dependent upon the capacity, as well as the self-induction of the oscillating circuit, so that the capacity must be as great as possible and the self-induction as small as possible. For an industrial installation it is, however, compulsory, in increasing the capacity, also to increase the self-induction in consequence of the self-induction of the condensers themselves, as well as the connecting wires which are used between the condensers.

In the employment of the rays for sterilization, chemical actions or other purposes, it is in many cases necessary, or at least desirably, to prevent the action of the oxidation of the nitrogen which takes place in the spark gap upon the substances to be treated with the rays. In such cases a film is placed between the spark gap and the substances to be treated which is transparent to ultra violet rays but keeping back the oxides. This may be effected by arranging a casing of quartz glass around the spark gap.

Diphtheria Toxin.

Lowenstein (Vienna Z. exper. Path. Ther. 15, 279, 1914) has concluded that ultra violet light renders diphtheria toxin atoxic. In 40 hours radiation from a quartz mercury vapor lamp 1,000 fatal doses were completely destroyed. The quartz lamp is about 30 times as active as the iron arc. In the concentrations used, radium has no effect on the toxin. The light alteration is deep-seated since the atoxin does not confer immunity but does sensitize. Toxin neutralized by antitoxin appears to form a combination which is slowly dissociated in the animal, resulting in the development of immunity. Over-neutralization of toxin does not change this phenomenon. Immunity thus developed requires 25-50 days. Injecting neutralized toxin confers about 25 per cent. immunity; i.e., 40 neutralized fatal doses injected into a guinea pig protect (after immunity develops) against 10 fatal doses of toxin. The height of the immunity so produced increases with the dose up to a maximum, while increased doses beyond that merely hasten the time of development. Partially neutralized toxin has no better effect than neutralized. The immunity of guinea pigs injected with over-neutralized toxin is greatly increased by an intracutaneous injection of one milligram of toxin.

ENZYMES.

Amylase and Invertase.

Chauchard and *Mazoue* (Comptes. rend., 1911, 152, 1709) have found that both amylase and invertase lose their activity when exposed to ultra violet light at a distance of 12 centimeters from a quartz mercury vapor lamp working at 110 volts. The decrease of the activity is rapid at first, then becomes slower. Amylase is more sensitive to the light than invertase, either alone or when the two enzymes are mixed.

Pepsin, Rennet, Laccase and Other Enzymes.

Agulhon (Comptes. rend., 1911, 398) exposed preparations of diastase and other enzymes in quartz tubes to ultra violet light, the source being a quartz mercury lamp using 2-3 amperes at 110 volts. The tubes were about 15 millimeters in diameter and 1 millimeter thick, and were placed 15-20 centimeters from the source. Tubes of glass of these dimensions were not penetrated by light of a wave length less than 3,022 Angstrom units. Tubes of glass and quartz containing preparations of the same materials were exposed to the light from one-half to six hours, and the relative activity of the contents examined. The activities of sucrase, amylase, emulsion, pepsin, rennet, and catalase were all reduced by the light which permeates quartz but not glass. Laccase and tyrosinase are attacked when their solutions in glycerol, are diluted with water. Peroxydase of malt is rapidly attacked under the same conditions.

Cell Colloids.

Burge, in a discussion of the mode of action of ultra violet radiation in injuring the refracting media of the eye (J. Frank. Inst. 1915, 477), states that the refracting media of the eye, cornea, lens, etc., are composed of cells containing a colloidal material or protein, of which egg-white is a good example. It is known that egg-white is converted into an opaque coagulum on exposure to ultra violet radiation, just as it is when it is heated to 100° C.

Free swimming unicellular organisms, paramecia, were exposed to the radiation from a quartz mercury burner and observed under the microscope during the exposure. The normal organisms are transparent; those exposed become very granular and opaque. The conclusion may be drawn that ultra violet radiation injures or kills living cells by coagulating the protoplasm or living material of the cells.

A normal excised crystalline lens was placed between two quartz plates and pressed into a thin layer by squeezing the plates together. By means of a quartz spectograph the spectrum from a quartz mercury burner was focused on the layer of transparent lens material for 30 hours. At the end of this time it was as transparent as at the beginning of the experiment. However, when the preparation was immersed in 0.1 per cent. calcium chloride solution, four bands of coagulated lens protein appeared where the bands of the spectrum had been focused. These bands are of wave lengths 249, 254, 265 and 280 respectively.

The further conclusion is drawn by Burge that the short wave lengths of the spectrum coagulate the living material of the cells by changing this material in such a way that certain salts (e.g. those of calcium) can combine with it to form a precipitate or coagulum, and that the effective wave lengths in case of the quartz mercury arc used are between 249 and 280 inclusive.

Treatment of Wines.

In discussing methods for artificially ageing wines, *Henri Helbronner* and *von Recklinghausen* (U. S. patent 1,130,400 March 2, 1915) state that the process of producing liquors of this class may be divided into two stages. In the first or fermentation stage, the wine is allowed to ferment in contact with air, while the second or ageing stage takes place in storage in casks or bottles. In this latter stage, the characteristic flavor is produced by the formation of various compounds, mainly ethers. When wine which has passed the fermentation stage is exposed in thin films to the action of ultra violet light, the taste and color of the wine is changed and it quickly attains the characteristics of old wine. The time of treatment is comparatively short, an example being given in which two and one half litres were treated in several minutes in a small apparatus, it being claimed that after this treatment the wine had the characteristics of a product several years older.

Before the war in France, it was reported that the use of ultra violet light for ageing wine was making substantial headway there and that it promised to modify the manufacture of this commodity in a highly advantageous manner. No information is at hand regarding the present status in that country.

The action of ultra violet rays on the alcoholic fermentation of India fig has been studied by *Romolo* and *De Fazi* (Ann. chim applicata 6, 221, 1916, Chem. Abs. 1917, 683). If the period of exposure to the rays be limited, saccharomyces opunitiae lives, reproduces itself, and is more vigorous than under normal conditions. Too long an action, however, is harmful, and the activity of the organism gradually decreases, and may be killed by the rays after many hours' exposure Must of India fig in ordinary fermentation forms an abundant film on the surface which increases in thickness from day to day, but if the fermentation takes place under the ultra violet rays, no trace of film is visible, even after many days.

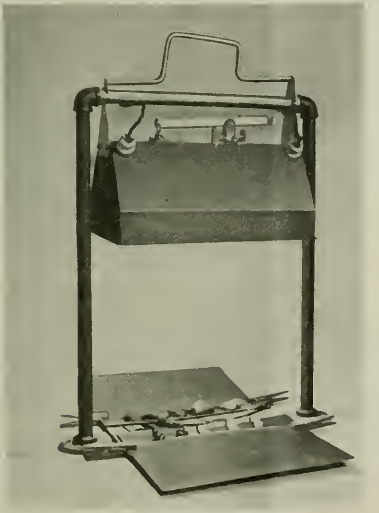
On red wines, ultra violet light has a pronounced bleaching effect. Grape-juice (red) rapidly loses its color on exposure to a source of strong ultra violet light.

Low Grade Flour.

In the writers' laboratory, samples of low-grade flour or midlings have been considerably bleached after an exposure of eight hours at about six inches from the lamp to the action of ultra violet light. The change is too slow to offer commercial possibilities.

Soluble Starch.

Massol (Comptes. rend. 1911, *152*, 902) states that if solutions of soluble starch (prepared by heating for 3 hours at 150°C.) of 0.2 to 1 per cent. concentration, are exposed, at a distance of 10 centimeters, to the action of a mercury vapor quartz lamp consuming 300 watts, the starch gradually loses the property of giving a blue color with iodine, the color undergoing an alteration similar to that observed when the iodine test is applied at various stages of starch conversion. The rate of transformation increases on decreasing the concentration and on acidifying the medium. As a result of the exposure also, the solution acquires reducing power and becomes less precipitable by alcohol; the portion soluble in alcohol possesses reducing power and is dextro-rotatory. Examination of the product obtained on exposing a solution containing 1.7 grams of soluble starch and 1.715 grams of sulphuric acid per 1,000 cubic centimeters to ultra violet rays showed that the reducing substance formed is probably maltose. A control experiment in which the solution, instead of being exposed to ultra violet rays, was heated to 72°C., showed that neither the acidity nor the temperature conditions are capable under the conditions of Massol's experiment, of effecting the transformation and the latter is therefore due to photochemical action.



Ultra Violet Color Tester.
(Courtesy of the R. U. V. Co., Inc.)

Testing of Dyes.

Scheurer (Bull. soc. ind. Mulhouse 1911, 80, 324) has compared the action of sunlight with ultra violet light produced by the mercury quartz arc on dyes When using ultra violet light the dyes were protected against the ozone formed. Benzo colors were hardly faded by sunlight, but in 24 hours by the mercury quartz arc they were materially changed. Indigo resisted mercury quartz arc light better than it did sunlight.

The R. U. V. Company* (private communication) have developed a laboratory apparatus for the testing of dyes for light fastness by means of ultra violet light. They state that there is no color which ultra violet rays will not fade and that there is little difference in the actual fading qualities of the colors if the matter of the depth of color is eliminated A large number of colors have been tested but details of these tests are not available at this time.

Gebhard (Farber-Ztg. 1911, 22, 6, 26) suggests that the present method of testing fastness of colors with daylight is unsatisfactory, due to varying atmospheric conditions and proposes using a cabinet with both an enclosed arc and a mercury quartz arc. The change of color whether fading or change to another tint is to be recorded by orthochromatic photography using a light filter of the same color as the original dyeings.

Absorption of Ultra Violet Light.

The absorption of ultra violet radiations by several chlorides of ethane, ethylene and acetylene has been investigated by *Massol* and *Faucon* (Compt. Rend. 1917, 308-10). None of the compounds studied showed the characteristic band of chlorine. Tetrachlorethylene absorbs more ultra violet radiations than hexachlorethane or acetylene tetrachloride. This difference in absorption is attributed to the difference in the saturation of the molecule.

Bielecki and *Henri,* (Chem. Zeit. Rep. 1914, 16; Ber. 1913, 3650) have made a study of the absorption of the ultra violet rays by saturated and unsaturated fatty acids. The results are given in a tabulated form and also in curves. The position of the double bond as related to the carboxyl group appears to be the deciding factor. The nearer the double bond is to the carboxyl group the greater the influence on the absorption. The cis form absorbs less than the trans form. The effects produced in various solvents were also studied.

Massol and *Faucon* (Bull. Soc. Chim., 1912, 11, 931-935) have made determinations on the absorption of ultra violet light by saturated fatty alcohols by means of a quartz spectograph. The light was supplied by an electric arc between a brass terminal and an iron one covered with an alloy of tin, lead and cadmium. Impressions on a photographic plate were obtained of wave lengths lying between 5,015 (green) and 2,100 Angstrom units. The liquids were enclosed in a glass vessel with quartz ends. The thicknesses were varied between one and one hundred millimeters. Methyl and ethyl alcohols proved very transparent. The transparency diminishes slowly with an increase of the thickness. With other normal alcohols such as butylic, amylic, hexylic, heptylic and melissic, the absorption increases very rapidly with the thickness. The transparency diminishes with the increase of the number of carbon atoms. The secondary alcohols behave in much the same way as the primary alcohols, but a secondary alcohol is slightly more transparent than the corresponding primary one. Tertiary alcohols are much more transparent for the same thicknesses. Methylpropanol, methylbutanol- 1.2 (optically active), and methylbutanol 1.3 (optically inactive) are less transparent than the corresponding primary alcohols. They show, with thicknesses of less than ten millimeters two absorption bands, one at the wave length of 2,500-2,600, the other at the wave length of 3,100 Angstrom units. These bands disappear when the thickness is increased above ten millimeters, because at that point all waves of a length less than 3,100 units are absorbed.

---

*50 Broad St., N. Y.

In a discussion of the liberation of point discharges by ultra violet light *Ferlach* and *Meyer* (Verh. deut. physik. Ges. 15, 1037, 1914) state that for both positively and negatively charged points in air the delay of the beginning of the discharge caused by exposure to ultra violet light decreased with decreasing pressure of air. This delay has only a secondary bearing on the photoelectrical effect. At the relatively low pressures employed the delay effect decreased with increasing intensity of illumination.

Nuclei Produced by Ultra Violet Light.

From experimental investigation with gases and vapors in a Wilson expansion apparatus the following conclusions were drawn by *Saltmarsh* (Proc Phys. Soc. London 27, 357, 1915). Nuclei produced in air by ultra violet light which has traversed a few centimeters of air are not affected by an electric field of 50 volts per centimeter. The nuclei are equally effective in producing condensation of water, toluene and turpentine vapors, and they are formed even by light which has traversed 50 centimeters of air. Alcohol vapor condenses without expansion on much smaller nuclei than water. No nuclei were formed by light in absence of oxygen or carbon dioxide. There was no trace of hydrogen peroxide in the clouds on nuclei. Oxygen containing ozone also contains nuclei for condensation having similar properties to those formed by ultra violet light. The nuclei can be destroyed by heating. It seems probable that the nuclei formed by ultra violet light do not cause condensation by virtue of any particular chemical change, but that they are particles large enough to act like dust particles as centers round which condensation can begin.

Photochemical Experiments of Baudisch and Furst.

Baudisch and *Furst* (Ber. 1912, *45*, 3426) have arrived at the following conclusions as the result of photochemical experiments. The change produced by light on the ammonium salt of alpha-nitrosonaphthyihydroxylamine is due to the action of violet and blue rays of comparatively long wave length which will pass through glass and other substances. If a piece of stout filter-paper be treated with the above salt, steamed, and exposed to the rays from a quartz mercury vapor lamp with a glass plate covering half of the sheet, it is found that the paper is uniformly reddened. The same result is obtained by using a gelatin plate or a solution of a starch or albumin. If, however, the filter paper is treated with a solution containing potassium nitrate or potassium iodide and starch and illuminated in the same way, it will be found to turn blue only where it is uncovered. The rays which cause the evolution of oxygen from potassium nitrate are of short wave length and are absorbed by various filters. It is suggested that the colloids of plant cells can exercise a similar differentiating influence on the radiation which they receive. From the above ammonium salt, free alpha-nitrosonaphthyhydroxylamine can easily be obtained by precipitation with metaphosphoric acid. It is soluble in chloroform but the solution gradually changes owing to the reducing action of the chloroform, which forms a-diazonaphthalene chloride.

Chlorination of Coal Gas.

To ascertain the possibility of using coal gas for the production of valuable compounds, *Bedford* (J. Ind. Eng. Chem. 1916, 1090) subjected a mixture of chlorine and natural gas, in a chamber containing blocks of ice, to the action of light from the white flame arc and obtained a heavy liquid beneath the water produced by the melting of the ice. This liquid consisted of methylene chloride, 35%; chloroform, 35%; carbon tetrachloride, 5%, and chloroethanes, 20%. A portion of the product, amounting to about 14% of the total, remained soluble in the water, and consisted of methylene chloride, 61%; chloroform, 28%; carbon tetrachloride, 1.5%, and chloroethanes, 6%.

Determination of Shells in Cocoa.

A method for the detection of shells in cocoa is described by *Wasicky* and *Wimmer* (N. Nahr Genussm. 30, 25-7, 1915). This method is based upon the difference in appearance between shell and nib tissue when viewed through a microscope by ultra violet light. The proper light is best obtained by means of a carbon-iron arc lamp, the light before reaching the mount being passed through a Wood-Lehmann filter (two blue Uviol glass cells, one filled with 1:12000 nitrosodimethylaniline, and the other with concentrated copper sulphate solution The color of the shell tissues when seen by this light is buff or brown, the mucilage cells being almost colorless or a light yellowish green. The nib tissues appear in various shades of blue-violet. The details of the method are as follows: Treat ten milligrams of the powder with ten cubic centimeters of alcohol-glycerol mixture (equal parts of each) and allow to stand for one hour. Centrifuge, pour off the liquid layer and add one cubic centimeter of borax-glycerol solution (1 gram borax, 15 grams glycerol) to the solid residue. Mix thoroughly and place one drop upon a Hartwich-Wichmann counting cell. View through a microscope by means of ultra violet light and count the number of shell particles visible over a given area. The per cent. of shells present can be ascertained by counting the shell particles in mounts of known composition prepared in the same way and comparing with the count of the unknown. The samples employed for comparison must have about the same degree of fineness.

Celluloid Substitute.

According to *Kuhl* (Reports of the Progress of Applied Chemistry issued by the Society of Chemical Industry, Vol. 1, 1916, 192 J.S.C.I. 1915, 623) the polymerization of vinyl esters (vinyl acetate or vinyl chloracetate) by ultra violet light yields solid masses which may serve as substitutes for celluloid and which are fireproof and odorless. The polymerization is assisted by catalytic agents (organic peroxides) to give thick syrups which on illumination give solid masses having valuable properties.

Vulcanization of Rubber.

Bernstein comments on the use of ultra violet light for the vulcanization of rubber (U. S. patent 1,240,116, September 11, 1917, as follows: Vulcanization by heat requires a considerable plant; the operation is a lengthy one, and does not permit the incorporation of compounds or substances which are decomposed by heat, such as for instance, leather and coloring matter. The use of sulphur chloride produces noxious effects upon the workmen, gives irregular results and does not allow chloride of sulphur such as, for example, lead oxide, lead carbonate, zinc oxide, etc. These various disadvantages are claimed to be avoided by exposure of the rubber mixed with sulphur, sulfids or other vulcanizing agents to the action of ultra violet rays by this process. Vulcanization can be hastened by the application of heat and pressure. In this case it is claimed to be unnecessary to utilize high temperatures, 65° C. to 80° C. being sufficient. The temperature depends upon the nature of the gum, viz: upon its degree of polymerization. The object in applying pressure is not only to hasten the vulcanization but also to prevent the formation of blisters upon the surface of the vulcanized compound. These blisters result from the expansion of air introduced into the compound during the process of manufacture and from the traces of moisture previously absorbed by the gum. In vulcanization by means of hot air it is necessary to incorporate accelerators in the mixture, such as lead oxide or magnesia, etc. In the case of photo chemical rays, however, the employment of these accelerators is claimed to be unnecessary, the superficial vulcanization progressing spontaneously toward the inner portion of the object under treatment so that the vulcanization becomes complete. The action of the photo-chemical rays appears to be catalytic in nature. The surface vulcanized by means of ultra violet rays protects the subjacent substance from any secondary reaction such as, for instance, its resinification. In order to avoid the formation of ozone produced by the action of the ultra violet rays the operation may be carried out in *vacuo* or in an atmosphere consisting of a neutral gas not containing oxygen. The time required for the vulcanizing process will depend upon the nature of the gum employed, the distance of the lamp or lamps from the surface under treatment, the nature of the substance and the power of the lamp or lamps.

A widely circulated newspaper report appearing some years ago stated that a man by the name of Blanco had exploded a case of dynamite at a distance of half a mile with an ultra violet ray apparatus. Blanco claimed that magazines of ships and gasoline tanks could be exploded by this means. This sensational report apparently has received no confirmation from reliable sources.

Photographic Effects.

Wood (Scientific American Nov. 15, 1913, 380) gives the results of experiments in photographing various objects by means of the ultra violet and infra red rays. With the ultra violet light a difference is shown in the quality of white in various white flowers. Photographs of the craters on the moon show new characteristics with ultra violet light. The vapors rising from a drop of mercury are easily visible when photographed by this method. It is also easy to determine erasures and changes in checks and legal documents which are invisible in ordinary light. The best ink eradicators show a dark smudge when they have been applied. Various screens and types of apparatus are described.

As an Illuminant for Photographic Purposes.

Mees (J. Frank. Inst. 180, 481, 1915; Chem. Abs 1915, 3180) recommends the following artificial illuminants for use in practical photography: For portraiture, flame arcs, Cooper-Hewitt lamps, and the nitrogen tungsten lamp; for motion pictures, the Cooper-Hewitt lamp, quartz arc, flame arc; for photo engraving and silver printing, flame arc, enclosed arc; for platinum printing, the Cooper-Hewitt lamp.

Transparency of Metal Solutions.

The ultra violet transparency of certain colored media is described by *Absalom* (Chem. Abs. 1917, 2556, Phil. Mag. 1917, 450) who states that many gems and minerals which are transparent in ultra violet light when colorless, do not lose their transparency in the colored specimens, nor is any effect noted on artificially coloring a specimen by means of cathode rays, although colored metallic salts and aniline dyes are opaque. This is strong evidence that the color of minerals is due to colloidal metals, especially in such cases as hyacinth (zircon) and yellow topaz which only begin to be opaque at 2617 and 2294 respectively Deeply colored solutions of the alkali metals and magnesium in liquid ammonia also are extremely transparent in the ultra violet, which tends to show that these metallic solutions are colloidal.

Comminution of Metals.

Schulze (Ber. physik. Ges., 1912, 246-57) states that experiments on the conversion of metals into dust by means of ultra violet light have negative results. Three different methods were tried.

Active and Passive Iron.

Allen (Faraday Soc., Nov. 12, 1913) states that iron which is chemically active shows a relatively large photoelectric activity, as it loses a negative charge fairly rapidly when insulated and illuminated by ultra violet light. Processes which render the iron passive greatly reduce this activity. These facts are in good agreement with the theory that the cause of passivity is to be found in the presence of a gaseous layer on the metallic surface. This theory, like the oxide film theory, was originally put forward by Faraday.

Peculiar Properties of Zinc.

Anderson and *Morrison* (Phil. Mag., 1912, *24*, 302) have stated that the surface of a metal, whether from oxidation or from some other cause, changes with lapse of time so as to make the metal more electronegative. For example the contact difference relative to a plate of uncleaned copper was 0.060 volt for freshly cleaned copper, 0.466 volt for uncleaned zinc, and 0.826 volt for freshly cleaned zinc. It has now been found that when exposed to a powerful source of ultra violet light, zinc becomes decidedly more electro-negative, the effect disappearing slowly when the source of light is removed.

Salts of Mercury.

Pougnet (Comptes. rend., 1915, 161, 348-351, J. S. C. I. 1915, 1053) exposed a 5% solution of mercuric chloride in a quartz tube 15 centimeters from a mercury vapor lamp working under 110 volts and 4 amperes. Almost immediately it became cloudy, owing to formation of calomel. After 30 minutes, 42% of the mercuric cloride had been decomposed and the calomel began to darken. After about 70 minutes when 48% of mercuric chloride had been decomposed, the reaction ceased. The reaction is reversible, one gram of calomel suspended in water and agitated during exposure yielding 0.635 grams of mercuric chloride in 6 hours; the action, slow at first, was accelerated as the suspended particles became finer. Most of the salts of mercury, especially when moist, are decomposed by ultra violet rays, and it is therefore advisable to keep them in bottles of orange-red color.

Formation of Perchlorates.

A process for the electrolytic formation of perchlorates is described by *Mack* (J. Phys. Chem 1917, 238), in which he states that chlorate may be oxidized to perchlorate in an acid solution by the use of sulphuric acid, ozone, and hydrogen peroxide. But when hydrogen peroxide is used hydrochloric acid is produced and interferes with the oxidation. The reaction may be carried out with oxygen if activated by the use of ultra violet light. The electrochemical formation of perchlorate is due to direct oxidation and the formation of the perchlorate at a potential far below that required for the continuous discharge of any ion present in the solution.

If chlorine gas is subjected to the silent electric discharge in a manner similar to that used in the preparation of ozone, a chemically active form of chlorine is obtained. The activity of this element is even greater than if subjected to the silent electric discharge and ultra violet light simultaneously. It has been supposed that under the influence of the electric discharge the chlorine forms a body analogous to ozone. It is, therefore, thought that the activity of the chlorine treated in this way depends simply on impurities such as air and water, as a result of which ozone or unstable chlorine oxide is formed. (Abderhalden, Handbuch der Biochemischen Arbeitsmethoden, Vol. IV., 870.)

Sulphur Oxychloride.

Trautz (Z. Elektrochem. 21, 329, 1915; Chem. Abs. 1915, 3008) states that the reaction $SO_2 + Cl_2 = SO_2Cl_2$ in the dark cannot be considered as a pure gaseous reaction. Only on the addition of animal charcoal as a catalyzer were easily reproducible velocity measurements obtained; then both reactions proceeded as absorption processes in which the velocity of diffusion did not appreciably interfere. In both cases the reaction is approximately normal, though more so in the decomposition than in the formation of the oxychloride. In the latter case the reaction constants decreased more rapidly, corresponding to a lower order of reaction (absorption). The temperature coefficient of formation is about 1, that of the decomposition about 1.5, though both values are too small on account of the slower temperature effect of absorption. The formation of the oxychloride from sulphur dioxide and chlorine in glass vessels under the light of a quartz lamp at 291° and at various concentrations has been studied. The reaction especially at the higher temperature proceeds smoothly as a second order reaction; the constants at the higher temperature are without variation. In the light, sulphuric oxychloride is not the only product of the reaction; if the relatively small periods of illumination are separated by several hours of darkness, other substances are formed which cause a decrease in the velocity constant of the reaction. When continuous illumination was employed, constants were no longer obtained, probably on account of the other products of the reaction. A temperature increase of 80° decreased the velocity of formation corresponding to a temperature coefficient of 0.88 for each 10°. The velocity of the formation-reaction is of the same order as that which is catalyzed by animal charcoal in the dark, whether "Uviol" light or that from a quartz lamp is used. The formation of sulphuric oxybromide from sulphur dioxide and bromide in the light of a Nernst lamp or in the dark, between 106° and 202° in glass vessels without a catalyzer, could not be accomplished. But carbon oxybromide could be readily formed from carbon monoxide and bromine vapor, an equilibrium being quickly reached which corresponded to a very large dissociation of the carbon oxybromide. From the equilibrium constants at 73° and 181° the heat of formation was calculated as about 3,000 cal.

(To be continued in the January issue.)

New Publications of the Bureau of Mines

(*List* 54.—*November*, 1917.)

Bulletins.

Bulletin 131. Approved electric lamps for miners, by H. H. Clark and L. C. Ilsley. 1917. 59 pp., 17 pls., 7 figs.

Bulletin 136. Deterioration in the heating value of coal during storage, by H. C. Porter and F. K. Ovitz. 1917. 38 pp., 7 pls.

Bulletin 141. Yearbook of the Bureau of Mines, 1916, by Van H. Manning. 1917. 173 pp., 17 pls., 8 figs.

Technical Papers.

Technical paper 167. Men who received Bureau of Mines certificates of mine rescue training, July 1, 1914, to June 30, 1916, compiled by D. J. Parker. 1917. 66 pp.

Technical paper 173. Coke-oven accidents in the United States during the calendar year 1916, compiled by A. H. Fay. 1917. 19 pp.

Technical paper 175. Production of explosives in the United States during the calendar year 1916, compiled by A. H. Fay. 1917. 24 pp.

Handbook.

Advanced first-aid instructions for miners; a report on standardization, by C. H. Halberstadt, A. F. Knoeffel, W. A. Lynott, W. S. Rountree, and W. J. Shields. 1917. 154 pp., 65 figs.

Note.—Only a limited supply of these publications is available for free distribution and applicants are asked to co-operate in insuring an equitable distribution by selecting publications that are of especial interest. Requests for all papers cannot be granted. Publications should be ordered by number and title. Applications should be addressed to the Director of the Bureau of Mines, Washington, D. C.

Aetna Explosives Co. Has Disastrous Explosion.

The plant of the Aetna Explosives Co. at Heidelberg, devoted to the production of trinitro-toluene, was wrecked by an explosion on December 5. Eight lives were lost and there were twenty-five injured. The explosion occurred in the drying department, in one of the eight 48,000-gallon tanks in which the explosive was being made. Losses exceeded $250,000. Windows were shattered throughout a section radiating 2 miles from the plant.

U. S. Bureau of Chemistry Wants Men

The Department of Agriculture is planning to conduct a special campaign to prevent grain dust explosions and fires in grain mills and elevators. For this work men are wanted with milling, mechanical or electrical engineering training and experience. (Salaries $1,440 to $1,800 per annum.)

Investigations will extend throughout the U. S., traveling expenses and subsistence will be provided. Those interested should address C. L. Alsberg, Chief, Bureau of Chemistry, Department of Agriculture, Washington, D. C.

Secretary Lane Names Six Chemists to Serve on New War Board

Because of the great amount of war work being done by the Bureau of Mines, Secretary of the Interior Lane has appointed six of the prominent chemists of the country to act as an advisory board to the bureau.

The members of this board are: Dr. Wm. H. Nichols, General Chemical Company, New York, chairman of the board; Prof. H. P. Talbot, head of the chemical department of Massachusetts Institute of Technology, Boston, Mass.; William Hoskins, consulting chemist, Chicago, Ill.; Prof. H. P. Venable, head of the chemistry department, North Carolina University, Chapel Hill, N. C.; E. C. Franklin, professor of chemistry, Leland Stanford University, Stanford, Cal.; and Dr. Charles L. Parsons, chief chemist of the Bureau of Mines.

The board will discuss and advise upon gas warfare research, the minerals especially needed for munitions, and the recently enacted law for the regulation of explosives.

Bureau of Mines to Enforce New Explosives Law.

Washington, November 11.—Any person in the United States found with explosives in his possession after November 15, and who does not have a license issued by the Federal Government showing the purpose for which the explosives are to be used, will be at once arrested and fined up to $5,000 or sent to prison for one year. If the circumstances warrant, the person may be fined $5,000 and in addition given the one year in prison.

Peabody to Assist Director Manning.

This is the principal clause in a war measure passed by the last Congress which is now being put into effect by the Bureau of Mines, Department of the Interior, which bureau has been charged with its enforcement. Francis S. Peabody of Chicago, a well known coal operator familiar with the use of explosives, large amounts of which are used in the coal mining industry, has been appointed by Secretary of the Interior Lane to act as assistant to the Director of the Bureau of Mines, Van H. Manning, in the enforcement of the law. Under the law, the director of the bureau is empowered to utilize the services of all United States officers and all police officers of the states, including the city police forces, county sheriffs, deputies, constables, and all officers in any way charged with police duties. The police of the cities have already been organized for this work, headed by a committee of chiefs of police in the big cities, of which Major R. W. Pullman, superintendent of police of Washington, D. C., is chairman. The police are not only to look after the enforcement of the law, but are also to make thorough investigations of all dynamite outrages and fires in factories and warehouses, and to make their reports to the Director of the Bureau of Mines.

Law Affects Possessors of Explosives.

Persons apprehended in plots to blow up factories and bridges will be turned over to the authorities for prosecution under Federal or state laws. Most states have specially severe punishments for these crimes. New York has an extreme penalty of twenty-five years' imprisonment for the placing of dynamite with intent to blow up property. The penalty provided in this Federal war measure is merely to cover the illegal possession of explosives.

The law provides that everyone who handles explosives must have a license. The manufacturer, the importer and the exporter must have licenses issued by the Bureau of Mines in Washington. The seller of explosives and the purchaser of explosives must also have licenses, these to be issued generally by county clerks, or other local officers who are authorized to administer oaths. There will be at least one licensing officer in each county, and more agents will be designated if the county is sufficiently large to warrant it. If a state has laws providing for a system of licensing persons manufacturing, storing, selling or using explosives, the state officials authorized to issue such state licenses shall be designated as Federal licensing agents; also city officials qualified to issue city explosives licenses will be given authority to issue Federal licenses. A Federal license will not relieve any person from securing licenses required under state laws and local ordinances.

In each state there will be appointed a state explosives inspector, who will represent the Bureau of Mines in the administration of the law within the state.

Only citizens of the United States or of countries friendly to the United States and the Allies may so obtain licenses.

Contractors, mining companies, quarrymen and others using large quantities of explosives, which are handled by employees, may issue explosives to their employees only through those employees holding a license, called a foreman's license.

The purchaser of dynamite, in obtaining a license, must state definitely what the explosive is to be used for and will be held accountable for its use as stated and the return of any explosives that may be left.

With the strict enforcement of this law, the Federal authorities hope to prevent explosives falling into the hands of evilly-disposed persons and to put a stop to all further dynamite plots.

British Exports of Dyestuffs.

It is rather astonishing that Great Britain, despite the difficulty of adequately meeting the requirements of her own dyers, should still be able to ship abroad considerable quantities of both natural and artifical dyestuffs. And yet she is doing this regularly and in increasing amounts. The detailed reports show that during 1916, coal-tar colors were exported to the extent of 3,225 short tons, valued at $3,298,000. Similar exports for 1917 were 2,017 tons, valued at $1,311,000. Switzerland was the chief purchaser, taking 1,348 tons—probably aniline or intermediates. British possessions took 996 tons and the United States 370 tons.

Natural dyestuffs were exported to the extent of 6,755 short tons, valued at $2,046,000. In 1915 the exports were 9,460 tons. Russia, Australia, Canada, the United States and Portugal—in the order named—were the trading purchasers.

Examination of Pigments.

Several recent contributions to the methods of testing pigments are of value in connection with the manufacture of lakes from coal-tar compounds. The most important are the following:

Physical Characteristics of Pigments and Paints, H. A. Gardner, Oil & Col. Tr. J., 1917, *51*, 1054.

Physical Properties of Pigments which Affect the Permanency and Efficiency of Paint Coatings, M. McNaughton, Paint, Oil & Drug Rev., 1917, *63*, No. 24, 6.

Use of the Flame Arc in Paint and Dye-Testing, W. R. Mott. Reprint of a paper read at the 28th general meeting of the American Electrical Association, San Francisco. Application may be made to Joseph W. Richards, South Bethlehem, Pa. This article contains many references to the literature on the subject.

Eimer & Amend Erecting New Home.

Eimer & Amend, 211 Third avenue, New York, manufacturers of chemicals and apparatus, have acquired a factory building at 13-17 Margaretta street, Newark, N. J., and are planning for extensive alterations and improvements. This company is also erecting a new building on Third avenue, between 18th and 19th street, New York, which will cost about $150,000.

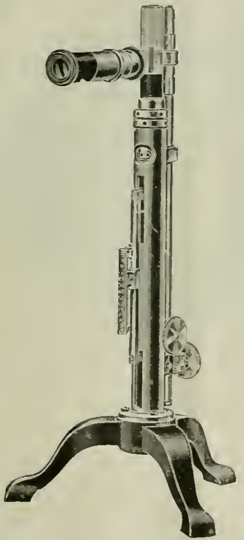
Synthetic Tanning Agents, M. Wade, London, (British patent 18,174, of 1915) prepared different synthetic tanning substances by condensing formaldehyde, or substances yielding it, with amino-naphthol-sulfonic acids, dioxynaphthalene-sulfonic acids or mixtures thereof, in aqueous or slightly acid solution, at ordinary or raised temperatures. The products can be used alone or with other tanning materials,

NEW APPARATUS

Conducted by F. W. S.

From month to month the newest forms of apparatus of interest to chemists and chemical engineers will be described and illustrated in this department. Information as to where various articles can be purchased may be obtained by addressing The Chemical Engineer, 118 East Twenty-eighth Street, New York City.

Specific Gravity Apparatus for Diamonds and Precious Stones



New Form of Apparatus for Specific Gravity Determinations.

The apparatus illustrated below is used for determining the specific gravity of diamonds and other precious stones, as well as so-called "Black Diamonds" and various crystals, minerals, etc. It consists of a metal stand with an arrangement provided at the top for moving a metal rod up and down. The exact position of the metal rod at any instant is shown by a scale at the side.

The metal rod is of an exact diameter, so as to occupy a definite space. The rod moves up and down in packing which is of liquid type. Surrounding the upper part of the rod is a glass tube which is also liquid type at the bottom. The small telescope shown at the top of the instrument is provided with cross hairs for exactly determining the position of the meniscus of the liquid.

To operate the apparatus the glass tube is filled with any desired liquid, in most cases, alcohol, to a definite point as determined by the telescope. The sample to be tested is then placed in the solution. The central rod is next lowered by means of a screw at the side until the meniscus stands again at exactly the same level as before, as determined by the telescope. The exact space occupied is then read on the scale at the side with the help of the Vernier, as designed by Professor Meade, of the University of Wisconsin. This space, divided by the weight in grams, gives the specific gravity of the sample.

A New Safety Crystal Which Cracks But Does Not Break

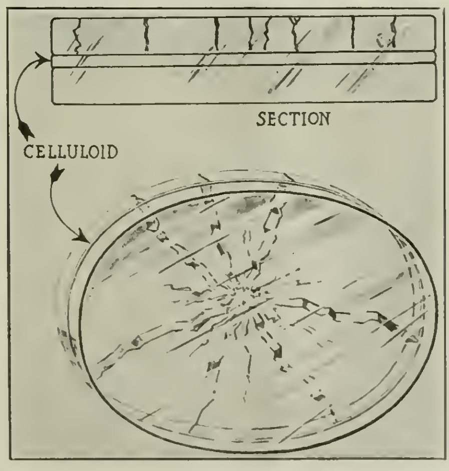


Diagram of Cross Section Illustrating the Construction of New Safety Crystal.

Of interest to the chemical engineer quite as much as to the practical workman or chemist is a new safety glass which has been developed by a New York firm and which bids fair to have a wide application in connection with industrial masks and goggles used for protective purposes to shield the eyes of the workman from flying particles, dust, heat or injurious gases.

The big feature of this new glass is the fact that while it can be cracked, it cannot be broken, even with a hammer blow, while in cracking there is no flying of splinters to jeopardize the eyesight of the workman. The fact that even when cracked the glass remains perfectly gas and water tight goes a long way toward

Government Paper on Specifications for Motor Gasoline

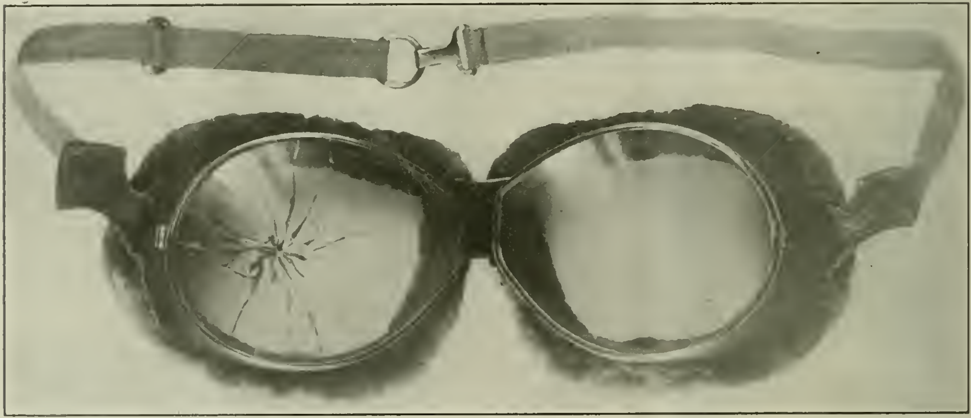
Responding to the many demands from state and municipal legislative bodies regarding specifications for the regulation of the quality of gasoline, the Bureau of Mines, Department of the Interior, has issued Technical Paper 166, "Motor Gasoline; Properties, Laboratory Methods of Testing and Practical Specifications," by E. W. Dean.

The paper gives information obtained by the bureau in the course of its investigations dealing with gasoline and aims to aid technical men representing producers and consumers of motor fuel in establishing convenient and satisfactory methods of testing and in interpreting analytical results in a practical way.

The present gasoline situation is confused by the existence of contradictory views as to the true index of quality of motor fuel. These views vary all the way from belief that a simple gravity test furnishes an adequate index of quality to claims that there is no practical test of gasoline except that of actual use Confusion also exists because of the variety of types of gasoline now sold and there are disputes as to the relative desirability of products derived from different types of crude oil and through different processes of refining. In some instances gasolines are condemned on account of properties that do no harm and in other cases high ratings are given products actually of low grade Adequate methods of analysis, though simple, are of fairly recent development and are not satisfactorily described in the literature. In addition there is more or less vagueness about the proper way of interpreting results even when the method of analysis has been satisfactory. The present paper does not pretend to be absolutely comprehensive or highly scientific, but treats in a practical way the problems and difficulties just mentioned.

Laboratory methods for the distillation of gasoline are discussed in detail and reasons given for the choice of the method adopted. This is practically the same as that recommended by the American Society for Testing Materials, in connection with the analysis of turpentine substitutes. The method is simple and rapid and is already in more or less general use.

A typical set of specifications is furnished, omitting, however, definite temperature limits, which should be decided upon only after consideration of local conditions. Methods of analysis, particularly of distillation, are described in detail.



Coggles Showing One of the New Crystals Cracked Without Splintering of the Glass.

New Safety Crystal

(Concluded from page 75)

recommending its use in place of the ordinary glass crystal, for it lends an added element of safety.

"Resistal" is the trade name of the glass used in the manufacture of these safety goggles and masks and its construction is made plain by the accompanying sketch. It comprises two layers of perfect optical glass which may be either flat or curved, with a layer of celluloid interposed, the whole being welded—not cemented—into a solid mass.

The result is a crystal that has every virtue possessed by the plain glass with none of its dangers or drawbacks; and it has, moreover, the strength and safety features of the celluloid "light," but unlike celluloid, it is absolutely unscratchable, is rigid and perfectly fireproof. Neither is it affected by water, heat or cold and the celluloid acts as a heat-insulating medium between the surfaces effectively preventing "clouding up" due to moisture condensation.

As a testamonial of the worth of the new crystal is the fact that goggles fitted with the safety glasses have been adopted for the needs of the Aviation Corps, U. S. Army, while from the same quarter the makers have received orders for a large number of crystals for military mask manufacture.

FOREIGN TRADE OPPORTUNITIES

These Opportunities for Foreign Business Relations Are Made Public by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce, Washington, D. C. Names, Addresses and Details May Be Obtained from the Bureau or Any of Its Branches. Refer to the Number of Each Opportunity and Place Inquiries for More Than One on Separate Sheets.

Saccharine.

25752.—A society in England desires to purchase saccharine. Quotations should be made f. o. b. United States port. Payment will be made by cash against shipping documents. References.

Paints, Colors, Varnishes, Glue.

25778.—An agency is desired by a commission agent in Spain for the sale of paint brushes, paints, varnishes, colors, coloring materials, glue, and enamels. Correspondence should be in Spanish. References.

Dyestuffs.

25712.—An agency is desired by a man in France for the sale of dyestuffs. Goods should be packed in cases or casks. Samples and price lists should be submitted. Correspondence should be in French. References.

Caustic Soda, Aniline Oil, Acetic Acid.

25707.—A firm in England is in the market for caustic soda, all chemicals such as glacial acetic acid, etc., aniline oil, and antimony, put up in 1-hundredweight casks or drums. Quotations should be made f. o. b. New York. Payment will be made by cash in the United States. Reference.

Dyestuffs and Tanning Products.

25698.—A firm in France desires to purchase or secure an agency for the sale of chemical products, dyestuffs, tanning products, petroleum, and oils. Payment will be made against documents. Correspondence should be in French. Reference.

Copper Sulphate and Sulphur.

25552.—A company in Portugal wishes to secure an agency for the sale of sulphate of copper, pure 99 per cent, sulphur in bags or bulk, and rough chemicals in general. Quotations should be made f. o. b. New York. Confirmed credit will be opened by cablegram. Correspondence should be in French. Reference.

Explosives, Dyes and Tanning Materials.

25557.—An agency is desired by a man in Peru for the sale of textiles, chemicals, explosives, dyes, and tanners' supplies and machinery. Payment will be made by draft against documents, sight or 90 days. Correspondence should be in Spanish. References.

Glycerine.

25484.—A merchant in Algeria desires to buy five or ten thousand kilos of glycerine at 30°. Correspondence should be in French. References.

Copper Sulphate.

25431.—A man in Switzerland is in the market for a large amount of sulphate of copper. Correspondence in French preferably. References.

Ammonium Chloride, Ammonium Carbonate.

25316.—A firm in Genoa is in the market for sal ammoniac and carbonate of ammonia. Correspondence should be in French or Italian. References.

Dyestuffs and Chemicals.

25335.—A woman in France desires to secure an agency for the sale of American products, especially salt meats, oils and greases, hosiery, woolens, chemicals, dyestuffs and shoes. Correspondence may be in English. She is willing to deposit money in local bank for guaranty of payment. References.

Coal Tar, Anilines and Chemicals.

25504.—A man in Portugal is in the market for coal tar, drugs, anilines, chemicals, varnishes, etc. Quotations should be made f. o. b. New York. Payment will be made against delivery of documents or by confirmed letter of credit. Correspondence may be in English.

Potassium Chlorate.

25496.—A firm in England is in the market for powdered chlorate of potash for the Bombay and Calcutta market. Quotations should be made f. o. b. New York. Payment will be made by cash in New York. The potash should be put up in kegs or cases of one hundredweight with calico and paper lining.

Coal Tar from Gas Works.

25340.—A company in Italy wishes to purchase coal tar, or gas coal pitch in large quantities. This product is the refuse obtained from distilling coal tar in gas manufacturing and should be dried. For payment, credit will be opened in American bank. The tar or pitch should be shipped loose and preferably "in ballast." Correspondence may be in English. References.

DISTILLATES

News Notes of Chemical and Allied Industries

General Glass Products.

The J. O. Jensen Company, Geneva, N. Y., has been incorporated with a capital of $50,000 to manufacture glass products. The incorporators are J. O. and C. A. Jensen and J. Henle, Geneva.

Community Chemical Company.

The Community Chemical Company has been incorporated at Dover, Delaware, with a nominal capital of $5,000 to manufacture chemicals. The incorporators are L. B. Phillips and J. B. Bailley, Dover.

Paints and Oils.

Paints and oils will be manufactured by N. Z. Graves, Inc., at Philadelphia, Pa., following the recent incorporation of this firm with a nominal capital of $5,000. Nelson Z. Graves, Philadelphia, has been named as the principal incorporator.

Glass Specialties.

The King Glass Company, Kokomo, Ind., has been recently incorporated with a capital of $100,000 to manufacture glass specialties of various kinds. The incorporators are E. B. King, C. D. Wells and William M. Wells.

Paints and Chemicals.

With a capital of $220,000, the Markleed Chemicals Corporation has been incorporated at New York, N. Y., to manufacture chemicals and paints. The incorporators are L. H. Marks, New York; H. C. Aron, 55 West 10th street, New York, and H. M. Wise, Woodcliff, N. J.

New Chemical Manufacturers.

Chemicals will be manufactured by the Provident Manufacturing and Chemical Company, Los Angeles, Cal., which was recently incorporated with a capital of $10,000 by H. C. Hollins, Frank Hollins and D. W. Coons, Los Angeles.

Fore Chemical Works Incorporated.

Under the laws of New Jersey the Fore Chemical Works, Jersey City, have been incorporated with a capital of $497,000 to manufacture chemicals. The incorporators are M. W. Alexander, R. E. Breed and U. M. Fleischman.

Electrosynth Chemical Company.

With a nominal capital of $5,000 the Electrosynth Chemical Company has been incorporated to manufacture chemicals at New York, N. Y. The incorporators are J. M. Winston, H. and M. Abrams, 130 West 113th street, New York City.

New Plant for Potash Manufacture.

Mason Brothers, of Sausalito, Cal., have acquired 90 acres of land at Antioch, that state, and will erect a $500,000 plant for the manufacture of potash, acetone, ammonium sulphate, etc.

Heller & Merz Will Erect Two Buildings.

The Heller & Merz Company, Hamburg place, Newark, N. J., manufacturer of colors, dyes, etc., has awarded contracts for the erection of two new one-story brick factory buildings to cost $56,000.

Raritan Copper Works Adds to Plant.

The Raritan Copper Works, Perth Amboy, N. J., has completed the construction of a new two-story addition to its plant. The new structure is estimated to cost about $24,000.

Beckers Works Still Growing.

The Beckers Aniline & Chemical Works, Inc., East Eighty-third Street, Brooklyn, N. Y., is making rapid progress in the construction of new additions to its plant in the Flatlands section. The estimated cost is about $1,100,000.

Will Build New Retort House.

The Stackpole Carbon Company, 71 West Broadway, New York, has awarded a contract for the construction of a new one-story retort house at Mary's, Pa., to cost $30,000.

Chemicals of All Kinds.

The Staier Chemical Company, Newark, N. J., has been incorporated under the laws of that State with a capital of $50,000 to make and deal in chemicals of all kinds. H. Staier and J. C. Staier, both of New York, and F. W. Miller, of Newark, are the incorporators.

Brown-Ferres Co. Will Build.

The Brown-Ferres Company, Inc., Newark, N. J., manufacturers of phenacetine and other chemicals, have acquired a two-story reinforced concrete factory building on Meadow lane. The company is planning for the immediate erection of a new building about twice the size of the one just acquired.

Chemicals and Chemical Compounds.

The Compound Specialty Company has been incorporated with a capital of $50,000 at New York, N. Y., to manufacture chemicals and chemical compounds by S. Baer, 1286 Lexington avenue; M. L. Schaller, 176 West 87th street, and J. R. Roth, 180 St. Nicholas avenue, New York.

General Chemical Co. Builds Homes.

The General Chemical Company has commenced the construction of a block of thirty-nine dwellings for the workmen employed at its plant at Wilmington, Del.

Brown Considers Erection of Carbon Plant.

Alton Brown, of Pittsburgh, Pa., and those associated with him, have acquired 700 acres of land at Monroe, Louisiana, and are considering the construction of a $700,000 plant for the manufacture of carbon.

Salem Co. Adds to Plant.

The Salem Oil and Grease Company, Salem, Mass., is constructing an addition to its plant, and is planning to install new tanks and machines for the production of oils for leather tanners.

New Benzol Plant at Minneapolis.

The Minnesota Steel Company, Minneapolis, Minn., is engaged on the erection of a new benzol plant at that city in which it is expected that operations can be started before the close of the year.

New Bureau of Mines Study on the Coking of Illinois Coals

The Bureau of Mines, Department of the Interior, in co-operation with the Illinois State Geological Survey and the Department of Mining Engineering of the University of Illinois, has completed a study on the coking of Illinois coals, and has published the results of this investigation in Bulletin 138, by F. K. Ovitz.

Mr. Ovitz, in discussing the subject, says:

"In its endeavor to promote a more efficient use of coal the Bureau of Mines, in co-operation with the Illinois State Geological Survey and the University of Illinois, has undertaken an investigation of the coking of Illinois coals. The investigation was started by collecting from various sources the data regarding experiments already made by others; these data have been compiled and are presented herein.

"The present methods of using coal seem wasteful. When coal is burned in furnaces for the generation of steam, only the heat generated by the fuel is utilized; possible by-products are not only lost, but frequently are the source of the smoke nuisance. The volatile matter containing the tar and heavy hydrocarbon gases is difficult to burn completely in many furnaces, and its decomposition produces black smoke. When coal is coked in a by-product oven, the volatile matter is no longer a nuisance but, on the contrary, is the source of many by-products, including benzol, toluol, gas, tar, ammonia, and cyanogen, all of which increase the value that may be obtained from coal.

"The coke that remains after the volatile matter has been driven off is a valuable fuel that can be used for almost all purposes for which bituminous coal can be used, and it is necessary for some metallurgical work. It has about the same heating value as anthracite coal. Because of its cleanness and its burning without smoke, it is well suited for domestic heating and the generation of steam in plants where smokelessness is demanded. The use of coke for these purposes would do much to eliminate smoke in cities. The best grades are regarded as essential in many metallurgical processes for reducing ores to their metals.

"By-product coking in the United States during the past three years has increased greatly. When the ovens now in course of construction are completed, the total capacity of by-product ovens will be more than double what is was in 1913. This increase has led to a search for coals other than those now known to be available for use in by-product ovens. Tests with coals from the southern part of Illinois have indicated that coke from Illinois coal unmixed with other coals can be used for fuel purposes and that coke from mixtures of Illinois coal with low-volatile coking coal might be suitable for some metallurgical work. In the tests the yield of ammonia was larger than is obtained from Eastern coal.

"Evidently the development of methods by which good coke can be made from Illinois coals and the by-products recovered is a matter of high importance. Any investigation that will indicate how, by proper treatment, these coals can be made available to supply the market for coke and gas in the Middle West will increase efficiency in their use, and will aid in conserving the country's supply of high-grade coking coal.

"The first part of this report outlines the present factors in the problem of coking Illinois coals and points out the future prospects. The quality of coke from Illinois coals alone, and from mixtures of Illinois coals with low-volatile coals is described, and the uses for which the coke is suitable are discussed. The gas-making properties and the value of the coals for making by-products are noted. Desirable methods of preparation of the coals, the impurities in them, and the effect of the impurities on the value of the coals for coke and gas making are considered.

"The second part of the report deals with the character of Illinois coals, their nature, physical properties, and chemical composition. The nonhomogenous structures of the coal, the variation in composition of different beds, and even of the same bed in different localities are pointed out. Those districts in which the coals contain the smaller amounts of impurities and are more favorable for coking are grouped together.

"The last part describes the tests made and gives detailed results. The tests are considered under three classes—those with beehive ovens, those with by-product ovens, and those with gas retorts. The details are as complete as the material available permits. The results of a few tests of the coke for furnace or other use are given."

Copies of this bulletin may be obtained free of charge by addressing the Director of the Bureau of Mines, Washington, D. C.

Madero Bros. Repudiate Employee's Action

Vigorous action on the part of officials of Madero Brothers, Inc., the well known importers and exporters of chemicals, New York, will, it is likely, be taken to clear away the blot upon the firm's reputation which, for a few hours, threatened them as a result of the arrest of Tonko L. Millic, of the firm's chemical department, and said to be an Austrian citizen, in connection with the alleged substitution of thirty-two cases of salicylic acid in place of quinine which had been ordered for use in an Italian military hospital.

At the time this issue went to press, Millic was being held at New York police headquarters on the specific charge of grand larceny, it being alleged that he misappropriated $25,000 in connection with the transaction. The cases in question, which were labeled "Quinine," were seized by officers of the Army and Navy Intelligence Service at Pier 7, Brooklyn, N. Y. Millic's arrest followed.

Head of Firm Hurries Back.

Ernesto Madero, the firm's president, who was in the South, was immediately reached on the long-distance telephone and started back for the New York office at once. Pending his arrival, other officials of the company declined to discuss the affair in detail.

When interviewed by a representative of the Chemical Engineer, Jose Miguel Bejarano, of Madero Brothers' chemical department, declared that a full statement would be forthcoming upon Mr. Madero's return.

Affair Does Not Affect Firm.

"Mr. Madero is expected to arrive within two days at the latest," said Mr. Bejarano. "The present officials of the company do not feel themselves authorized to make a statement until the arrival of the head of the firm."

"The only assertion they can make," he continued, "is that the present unfortunate affair is one concerning exclusively an employee of Madero Brothers, and not affecting the firm in the least."

It is alleged that Millic received the check in payment for the shipment of "quinine" and deposited it to his own banking account. Although no direct statement was made, it is rumored that drastic action of some description toward clearing away the temporarily implied stigma will follow.

Western Manufacturing Company.

The Western Manufacturing Company has been organized at Newark, N. J., to manufacture wood chemicals. It will operate a plant at 615 South 19th street for that purpose.

AMERICAN COLOR MANUFACTURERS AGREE TO "SEE IT THROUGH"

By Laurance T. Clark

Characterized by a Lack of Friction and a Unanimity of Purpose Which Surprised Not a Few of Those Who Attended, the Convention of Dye Manufacturers and Dealers Held in New York Successfully Demonstrated Itself to Be Based Upon an Idea Which Is Fundamentally Sound, and Brought About the Organization of the Industry in America. A Detailed Account of the Transactions, Accompanied by the Various Addresses in Full, Is Contained in the Present Article.

Agreeing definitely to meet again on Wednesday, March 6, for the purpose of completing a permanent organization, the long-heralded gathering of some 200 dye manufacturers and dealers held in New York, adjourned after a conference which lasted two days and which was characterized by a striking lack of personal jealousy as well as a very marked spirit of mutual confidence and willingness to throw aside immediate individual interests for the common good.

When the color men again convene a certificate of incorporation will have been prepared and filed for the prospective association, and they will be presented with a tentative constitution and by-laws for consideration and adoption. They will also hear a report from a special committee which will be appointed to confer with the United States Tariff Commission on the subject of duties on intermediates and dyestuffs after the war, and will be invited to select a name for the new trade body.

"Dyestuffs Association of America."

This preliminary work will be performed between now and March 6 by the Organization Committee, of which Dr. J. Merritt Matthews, consulting chemist for the Grasselli Chemical Co., New York, is chairman. Some of the names suggested to the committee for selection were "Dyestuffs Association of America," "American Dye Manufacturers' Association," "National Association of Dyestuffs Manufacturers" and "American Dyestuffs Association." This last was objected to because the initials are the same as those of the American Druggists' Association. The first of these was finally selected.

If the recent convention is any criterion, this youngest of industrial organizations already reveals vast potentialities for efficiently concerted action which augers well for the future of the industry in this country. It was not that differences of opinion were totally wanting, but that they were so logically and rapidly straightened out to the satisfaction of all parties concerned, which gives eloquent testimony to the presence of a universal desire to subordinate personal preference to the best interests of the trade at large. A striking indication of this was the almost unique fact that after very thorough discussions each vote taken was, without exception, unanimous.

Manufacturers vs. Dealers.

The convention was opened by H. Gardner McKerrow, of E. F. Drew & Co., Inc., to whom credit is principally due for an amazing amount of energy spent in getting the representatives of the industry together under one roof for the first time in its history. Very early in the meeting the inevitable question arose as to the relative status of manufacturers and dealers. This immediately led to one of the day's most important discussions, which is taken up in detail further on, and which finally culminated in the two bodies meeting separately for a short while at the suggestion of B. P. Donnelly, of the Holland Aniline Co., Holland, Mich.

As the result of an interchange of views between two committees representing these interests, it was finally voted that membership in the organization is to consist of two classes; the first, or active members, comprising manufacturers of intermediates and dyestuffs, and the second, or associate members, consisting of the dealers. It is probable that there will be added to these a third class composed of representatives of allied interests and including makers of chemicals, makers of machinery, trade publications and the color using industries generally.

Dealers Will Have No Vote.

According to a decision reached at the convention, dealers will have no vote in the organization, but will have one of their number as a member of whatever executive body may be appointed to administer its affairs. It is expected that the third class will pay only nominal dues and will have the privilege of attending the public meetings of the organization, the use of its secretarial advantages, including all propaganda and statistical information, and in the case of the color users, the official information of the activities of the members, new colors produced, names of makers of special colors and general exchange service.

Rumford Hall, in the Chemists' Club building at East Forty-first street, New York, will again be scene of activities when the dye men come togeth

ANOTHER "DECLARATION OF INDEPENDENCE."

This is how the dye manufacturers of this country looked as they gathered to organize in Rumford Hall, New York, on January 22, 1918. No one who was present is likely to forget the taking of this picture. For the benefit of those who were not, we can only ask: How would you like to be told to "look pleasant" four consecutive times—and each time have the flashlight fail to work? No wonder Mr. McKerrow moved! Ten years from now this picture will be of historic interest, for it was the only one made of the gathering.

for what will be known as the first annual meeting of the association. The time set is 10:30 o'clock, and it is probable that the hospitality of the club, including the restaurant facilities, will again be extended to all delegates for the day. Judging from the numbers which availed themselves of this privilege, the action of the club directors was appreciated.

Officers and Committees.

Frank Hemingway, head of the well known firm which bears his name, was asked to preside over the convention, and after laughingly questioning the good judgment of those who approved him for the post, and expressing his failure to see "why Mr. McKerrow refused to hold his own baby at the christening," brought to the chair a personality which speedily revealed his ideal qualifications for this somewhat trying post.

Mr. Hemingway was unable to be present on the second day of the meeting, and David W. Jayne, of the Barrett Company, New York, who consented to act in his stead, also handled the meeting in an efficient manner. C. Cyril Bennett, publisher of a trade magazine, acted as secretary. Charles Jenkinson, of the National City Bank of New York, was chosen treasurer and went about the abhorred duties attendant upon this office in a manner which, it was voted, rendered them as nearly painless as it is possible for such things to be.

The organization committee consists of Dr. Matthews, chairman; Mr. McKerrow, L. A. Ault, of Ault & Wiborg, Cincinnati, Ohio; August Merz, of Heller & Merz, Newark, N. J.; W. S. Woodward, eastern manager for the Sherwin-Williams Co., New York; T. N. Hyndeman, of the Hydro-Carbon Co., Philadelphia, and S. R. David, of the National Aniline & Chemical Co., New York.

The committee which represented the manufacturers at the time of the separate meetings consisted of Dr. Matthews, Mr. Ault and Mr. Merz, while the dealers' committee comprised Bradford Webster, of the Dye Exchange Corporation, New York, J. M. Hollywood and J. F. Beatty.

The Speakers.

The speakers and their addresses, practically all of which are reproduced in full further on in the present report, were as follows: Mr. McKerrow, Mr. Hemingway, who spoke on the possibilities of rightly conducted trade organizations; Benjamin M. Kaye, an attorney who specializes on trade association formation, who outlined the proper legal procedure for organizing an industry; Mr. Jayne, who told of the recently organized Chemical Alliance; Dr. Edward Wallace Pierce, chief chemist of the U. S. Conditioning and Testing Company, New York, whose topic was "Standardization;" E. S. Chapin, of Boston, who pointed out the possibilities of conservation as a direct result of the prospective organization; Albert E. Parker, who had for his subject "The Patent Law and Its Relation to Dyestuffs;" Bradford Webster, an expert on trade arbitration, and Dr. Grinnell Jones, of the U. S. Tariff Commission. Dr. Allen Rogers, of Pratt Institute, Brooklyn, was also expected to address the convention, but was unable to attend.

THE CONVENTION IN DETAIL.

There was an attendance of about 125 manufacturers and dealers when Mr. McKerrow's gavel fell shortly after 10:30 o'clock on Tuesday morning, January 22. And if, unlike the shot fired at Fort Sumter in 1861, it was not heard quite " 'round the world," it is at least certain that it was heard as far away as Berlin.

Preliminary Steps.

He then proceeded to outline the various causes which had impelled him to take the initiative in bringing the various factors in the dye industry together.

"The fact of your presence here today," he said, "indicates your interest in the ideas which have called us together, and your attention is due to whatever it may appear wise to do in order to further the dyestuff industry and place it in its proper position as one of the important industries of our country. When I was asked by a number of gentlemen connected with the dyestuff industry and by several papers to take steps for the calling together of all who were legitimately interested in the manufacture and sale of dyestuffs, I objected on the grounds that there are others who have been much longer associated with the industry than I.

"I had, however, made some public recommendations regarding the advisability of standardizing Americon colors in an address delivered at Springfield in May, 1917, and December, 1912, and was assured that an effort to get together would be well received. The first letter received a response so extrordinary as to leave no doubt in my mind but that there was a widespread desire to establish and entrench the industry.

No Single Interest Responsible.

"From the first I have endeavored to impress upon all of those interested that this is a movement not instigated by any single interest, but a calling together of the trade as a whole in the hope that a crystalizing of the interests of all can be effected through sympathetic and concerted action for the benefit of all. I have had the co-operation of several gentlemen well known in the industry at several meetings during the past month, and have had an expression of their opinions as to the various points we discussed. After discussing these matters with Mr. Benjamin M. Kaye, who has been of great assistance, I decided that it was desirable, as was the original intention, that this should be simply a meeting to decide whether or not we shall have a trade organization, and, if so, to mark out the general lines on which it should be conducted.

"If we approach the question in the spirit of fairness and co-operation, with a single eye to consolidating and preserving what we have already won, free from any tendency to think that maybe our competitors individually are still working towards the same end, that of making our country free from foreign control

POST-CONVENTION COMMENT

H. Gardner McKerrow.

"The results of the convention should be a source of deep gratification to all concerned. There is no doubt but that an association of this kind was badly needed by the trade. The organization is now a reality, and the fact that every vote taken was unanimous is eloquent testimony to the unity of sentiment which animates it."

Charles Jenkinson.

"Speaking as an observer rather than an actual participator, there is every reason to feel optimistic over the future outlook for the new association. It can be best judged by the character of the concerns going into it, and already more than eighty first-class firms have taken an interest financially in the organization. I am certain there will be many more by March 6."

Dr. E. Wallace Pierce.

"The general program went through precisely as expected. It could not have been predicted in advance that such a sharp line would be drawn between manufacturers and dealers, but it is to be hoped that a closer union between the two will result. The association is going to eliminate from the dye business the irregularities which almost cost it the confidence of the consumer, and it is believed that it will bring about more amicable relations between producer and consumer, which cannot fail to result in better business."

(c) Underwood & Underwood, N. Y.

The Kaiser.

"A splendid example of American schrecklichkeit. Donnerwetter! Words cannot express my disgust at such proceedings. Have the Americans, then, sunk to such depths of depravity that they would thus defeat the aims of Kultur? I regard the whole affair as disgraceful, un-German, and therefore unthinkable, and may its perpetrators be properly punished for their wickedness. Gott strafe McKerrow!"

Scattered

"How is the disorganized effort of 130 American concerns going to meet the organized effort of 13 huge, active German concerns?"

—Benjamin H. Kaye

of one of our vital industries, and with all unworthy jealousies forgotten and laid aside, I am persuaded that we shall accomplish something."

"I take it that the first step to be taken is to effect a permanent organization and to this end we may proceed to the election of a chairman to conduct our meetings today and tomorrow. The election of this chairman, gentlemen, is up to you, but if it will be of any assistance to you in proceeding at this point, I would like to suggest that Mr. Frank Hemingway would make an ideal chairman, as he is a man who is well known and widely esteemed throughout many industries."

MR. HEMINGWAY'S ADDRESS.

Mr. Hemingway's nomination was promptly seconded and his unanimous election followed. Upon taking the chair he remarked that he hoped Mr. McKerrow had given more thought to the work ahead than he had to the qualifications of the proposed temporary chairman. "This matter is Mr. McKerrow's baby," he continued, "and just exactly why he refused to hold his own baby at its christening is something I do not understand, and I am free to confess that I think that both he and the gentlemen who helped him at the informal meetings held last week have made a very serious mistake in insisting upon my acting as temporary chairman at this meeting, as in the first place I have very few ideas of my own, and a most complete inability to express even these few."

"The gentlemen who insisted upon my acting as temporary chairman today have been frank enough to say that they want me because I do not count for anything in the industry, anyhow, and yet know a little something about it. It was thought dangerous to have, as the presiding officer here to-day, an important man representing any particular manufacturing interest, for fear the meeting as a whole should gather the impression that any large interest or interests proposed to run either this convention, or determine the policy of the National Dyestuffs Association, if and when formed, and, to an extent, I think they were right.

"If to-day you elect to form an Association which you may or may not choose to call the National Dyestuffs Association of America,—and, by the way, the latter is preferable, for the initials of the former are identical with those of the National Druggists' Association,—above all things, you must bring about an organization which is for the benefit of the industry as a whole and for all reputable manufacturers and merchants engaged in it, without regard to their size or importance, but with a very strict regard, on the other hand, to their repute and the seriousness and earnestness of their efforts.

"It is too bad that at the outset I am forced to say something which may not be very pleasant to Mr. McKerrow. It is too bad because I feel that the entire industry is very deeply indebted, indeed, to Mr. McKerrow for what he has already done in waking us all up to the crying need for the development of some organized co-operative effort. Mr. McKerrow has been so impressed with the necessity of standardization of products that he has called particular attention to this feature and, I think, created the impression among many of you that the main function of the

Focussed!

"Standardization is the big, burning question before this meeting."

—Dr. E. W. Pierce

association, if formed, will be the standardization of dyestuffs.

Standardization Not Most Important Point.

"He may set me right on this point later, but I think that Mr. McKerrow realizes that standardization is but one of the functions of an association, and by no means the most important. And now, gentlemen, I am going to say something to you all that will probably be horribly criticized, or lead you to believe that I have been associating with the Bolsheviki, and that is that, valuable as the formal procedure and official acts of a business association may be, they count for little as compared with the fact that the members of the association meet together and have a chance to discuss their common problems.

"It is a safe bet that most of you gentlemen here are members of two or three business associations and that you must realize how much time is wasted in meetings listening to the long and elaborate reports of committees and bureaus,—the Credit Bureau; the Fire Insurance Bureau; the Arbitration Committee; and so on and so forth.

Elimination of "Red Tape."

"The larger business associations realize this and print and distribute the deliberations of their committees so that correct action may be taken very quickly at the meetings, at which the problems are discussed, leaving more time to the members to meet together without any set order of business. In this way they have an opportunity, by friendly association and contact, to learn something of their own difficulties and to plan to solve them.

"We cannot solve our scientific and our technical problems by formal talks, nor can we devise general orders of business that will help to solve them. Our chemists work on their several problems, and, from time to time, come together to learn what progress has been made, and, in the end, the chemists and the engineers and the executive heads, familiar with all the problems and their solutions, together use their best intelligence to elaborate a successful working unit.

"At the meeting of the American Institute of Chemical Engineers last December I made so bold as to refer to the Gary dinners. We must admit that Judge Gary is an organizing genius and that he has faced the greatest industrial problems of this day when industry together with true progress blends with politics about as well as oil and water.

Organization Must Be Flexible.

"How often have we individually become enraged at some unpleasant little turn in a letter, only to find everything smooth out when, for the first time, we have met the writer thereof! I recommend to you gentlemen that if you form an association you form one that shall be flexible, and, above all, one that shall bring its members together frequently without too much routine or detail work for them to do. Let small active committees work out the solution of individual problems, but let the members meet often and acquaintanceship ripen into friendship.

"You manufacturers here to-day are tilling what is practically virgin soil in this country. To bring about competition and later to eliminate it by agreement in such a virgin field is to do something that is in the first place absurd and in the second place illegal. The powers that be, in Washington, have stretched the Constitution this way and that until it is now more or less out of shape, but I do not think the day will ever come when it will be illegal for men in this industry, or any other, to be friendly and to be familiar with their common problems.

"The Agricultural Department has placarded the South with the slogan 'Diversify Your Crops.' Is it not obvious that unless the farmers of the South come together, or are helped by some central body, such as the Department of Agriculture, they cannot very well determine just what to grow? They may all stop growing cotton and turn to corn. Then there would be a shortage of cotton and woeful competition in corn. You manufacturers want to 'diversify your crops,' but you have little or no opportunity of finding out what the other fellow is either making or preparing to make on a large scale. There is no need to elaborate on what happened with Aniline Oil and Phenol and a dozen other products, for you are all familiar with their history in the past three years.

Objects of Association.

"The next most important point for your consideration, I think, is the matter of the stated objects and the management of the Association. It is obvious that many manufacturers will hesitate to take an active part in the work of an association before they know the definite objects to which the association is committed, and, moreover, just exactly what qualifications are necessary for membership. The stated objects are not so serious, for when all is said and done associations of this kind are formed for the welfare of the industry as a whole, and, taking it by and large, that simple statement covers the situation.

Membership Qualifications.

"The matter of membership qualifications is, however, very serious, for I feel that no association should open its doors so wide as to admit to membership men who may plan to use the association for their own ends rather than to use their own knowledge and energy for the welfare of the association, which means the industry. Therefore, I think the most important of all the preliminary steps is the choice of the Committee that will bring about the formal organization of the association, and, at the same time, determine qualifications for membership, and, further, I feel that such a Committee should be a large and representative one.

Failure of Perkin's First Plant.

"I cannot express to you gentlemen the intense and personal interest I take in this development. Among my earliest recollections are some of the evidences of the failure of the British Dyestuff industry. Sir William Henry Perkin's first patent, which was entitled "Dyeing Fabrics" was dated August 26, 1856. Perkin's plant was erected at Greenwood Green, in London, and not long afterwards a plant was erected at Marsh Gate Lane, Stratford, London, E., by Evans, Kant & Co.

"These people at that time had the most up-to-date method for the manufacture of Rosaniline. They went along successfully for some time and then failed, and my father bought the property and used it for his own particular manufactures. In the Evans Kant Rosaniline process the oxidation was brought about by Arsenic Acid. The Aniline and Arsenic Acid were introduced together into a U shaped boiler and the mass was agitated mechanically while it was heated. One of these boilers produced in eight hours about a ton of magenta melt. In the last stages of the process lime was used to take up the arsenic and they obtained as a by-product very large quantities of arsenite of lime, very strongly colored with magenta.

Utilization of Apparent Waste.

"When I first saw that plant at the tender age of seven or thereabouts there was literally a hill of this material which spread a strong red liquor over the factory whenever it rained, and as you all know, it rains in England most of the time: and the first lesson I had of the utilization of waste products was what my father did with that hill, which stood just about where he wanted to place some furnaces. He took some of the material, washed it, levigated it, dried it and powdered it and sent samples to Prof. Riley in Washington and to Prof. Bessey in Ames, Ia., as a possible insecticide for use against the cotton worm which was then eating up most of the cotton crop in the South.

"The reports from Washington and Ames were so encouraging that my father made his first trip to this country in 1878. Prof. Bessey suggested to him as Paris Green was Green, this material, being purple and produced in London, should be called London Purple, and so it was named. I referred to the old books recently and found that long before the hill was demolished it had produced in profits an amount considerably in excess of what was paid for the entire property.

More Recent Achievements.

"I do not want you to think that to-day my sole interest in the industry is a fond hope that some mountains of valuable by-products will be forthcoming, for my benefit: for, as a matter of fact, my thoughts lie in one direction only, which is that American, French and English genius, intelligence, industry and energy should be enabled, by proper organization and adequate governmental co-operation to reach the success they deserve. No one can deny that the work already done and the results already obtained in this country are simply marvellous. There are made here today many of the most difficult pharmaceutical products, that three years ago we were told could never be made in this country. But the work is "spotty." The heads of the British dyestuff companies feel that under the most favorable circumstances possible it will be ten years at least before the perfection of organization developed by the German companies can be approached. Therefore, I repeat that to attempt at this early stage too much in the nature of detailed organization for an association, is to invite disaster, and to create greater confusion than already exists. It will be like attempting to instal an elaborate cost accounting system (and I speak feelingly and from experience) in a brand new industry, that has yet to produce its first commercial batch.

Relations with Government.

"Finally, there is the all important matter before you of a fair and helpful governmental attitude and, in this connection, let me read you six lines from an editorial on 'Science and Industry' which appeared in the 'Manchester Guardian' on June 30, 1917:

> " 'From ill-informed public opinion one cannot expect right minded public action. Any community that holds itself apart from the general body and is content to deplore the existing state of things without a vigorous effort to alter it is bound to suffer when public action comes to be taken.'

"Those lines to my mind are all-sufficient to justify you gentlemen in forming an active association. If you go ahead I pray you may succeed, and in any event I feel that we are all of us greatly indebted to Mr. McKerrow for the work he has done and for the great constructive effort he has made."

MR. McKERROW'S ADDRESS.

Mr. McKerrow then explained in detail all that might be accomplished through the formation of an association as follows:

"Mr. Chairman, Gentlemen of the Convention: When the suggestion was first made that the dyestuff manufacturers and dealers of this country should be invited to take part in this convention, the central idea which prompted the move was that of the advisability of devising some means for the standardization of American dyes.

"As the preparations for this meeting progressed, however, the initial idea expanded considerably until it became apparent that the first and most advisable step to be taken was to form a commercial association representing the dyestuff industry as a whole, and having under its care and jurisdiction not only the question of standardization, but other collateral questions of equally great importance to the industry, such as questions of tariff, patent law as affecting the dyestuff industry, arbitration of disputes, protection of contracts and other matters which, as the new industry becomes of more and more importance, call for treatment of an authoritative nature in the interests of all rather than the individualistic attention from diverse and divided interests which is all that such questions have received hitherto.

"To Be, or Not to Be."

"This, therefore, gentlemen, will be the first matter to be brought to your attention, the question as to whether we shall form a National Dyestuffs Association, and if so, the form it shall take, the duties it shall assume and the character of its government. It would appear that the right time to effect such a central organization is during the infancy of the industry, for it is then that the interests of all factors, both large and small, can be most equitably safeguarded and that the fundamental basis of its ultimate control can be established under such conditions as will best adjust themselves automatically to whatever its future growth may be.

Mr. Frank Hemingway.
Who Acted as Chairman of the Dye Convention

"As regards standardization, no definite conception as to how this could best be done was available at that time, but as the responses to the original invitation were almost without exception of an approving, and even an enthusiastic nature, and as they came from a very large proportion of those actively engaged in the industry, the idea began to take shape, and a great deal of expression of opinion took place; many experts in the dyestuff business were consulted; and others who had been identified with questions of standardization in other lines of industry were asked for their ideas.

Conflicting Views on Standardization.

"While the general idea of standardization was almost universally admitted to be something which it was eminently desirable to accomplish, a considerable conflict of opinion developed. By some it was characterized as an "iridescent dream," an ideal which is too far beyond our reach to attain; by others as a proposal which led to such complications and difficulties as to make it impossible of practical fulfilment; and still others did not hesitate to say that it was perfectly feasible and could be developed and carried out on perfectly proper and scientific lines if it was approached with an open mind and in a proper spirit.

Germany Did It.

"The opposition to it may be roughly classified as of three kinds,—first that of the man who honestly believes that it cannot be done, and in this regard I would remind you gentlemen, that it certainly was done by the German dyestuff manufacturers, and if it could be done by them, there is no conceivable reason why it cannot be done by American manufacturers. We have at the present time a complete list of probably less than one hundred aniline colors made in this country and these are for the most part of well recognized standard types, whereas it must be remembered that the standardization of German dyes included a line of upwards of one thousand colors, including not only distinct homogenous colors in themselves but a vast variety of compounds and mixtures and shades. It would not seem to be impossible, therefore, that at this stage of the development of the industry some effective means of laying the foundations for a system of standardization could be accomplished which would adjust itself to the future growth of the industry.

An Average, Workable Standard.

"It is not suggested that in establishing such a line of standards under the authorization of the National Association that the very highest types and strengths of colors produced should be adopted, to which all manufacturers would be expected to conform, but that an average, workable standard, which would be within the reach of all manufacturers honestly endeavoring to produce reliable goods, should be devised. It is quite possible that some offerings may run ten or even twenty per cent. higher than this standard, in which case the material offered would be worth relatively more money, while other offerings might be ten or twenty per cent. below the standard, in which case the manufacturer would be entitled to the value represented by his material or would be impelled to improve his method of production so as to reach the trade standard.

Standardization Will Aid Government.

"It is to be borne in mind further that it is practically indispensible to the purposes of the United States Government that some form of standardization should be adopted for the purposes of assessing and levying duties on imported colors.

"Wherever this duty takes the form of a specific rate, that is to say an impost of so much per pound, the question of the degree of concentration is immediately raised. There must be a starting point which the Government can adopt and against which importations can be compared for the purpose of determining the degree of concentration. It has been shown by past experience that dyestuffs can be imported of four and five times the concentration of ordinary recognized trade standards, and yet these importations carry no higher specific rate per pound than the trade standards as recognized before the war, thus defeating a very large proportion of the protective intent of the act. It is certain that if the dyestuff industry does not devise some means of standardization which the Government can adopt, an attempt to do this will be made by the Bureau of Standards in Washington. Would it not be far better, therefore, for the industry to devise a method of standardization which will be satisfactory to the Government, which will protect the interests of the dyestuff manufacturers and dealers, and which will, at the same time, also protect the interests of the consumers of dyestuffs, rather than leave it entirely to the functions of the Bureau of Standards, which would necessarily act in a more or less arbitrary way and simply with a view to facilitating the assessment of duties on imported dyes?

Negligible Opposition.

"Another species of opposition to the question of standardization has been from the purely technical interests in contradistinction to the practical interests. These gentlemen seem to be opposed to the idea chiefly on the ground that it has never been done hitherto and therefore that it is not amenable to accomplishment. This is the kind of opposition which inevitably confronts all new movements of this kind, and which can be safely left to take its proper place in the final consideration of the question.

More Sinister Motives.

"A much more dangerous and insidious opposition is that of those elements which seem to think that it is not to their interest to see any method of standardization adopted for American dyestuffs. Whether this is actuated by a belief that they themselves will establish and provide a standard to which all other makers will be compelled to align themselves or go out of business, or whether they have even more ulterior motives, and have an unexpressed idea of keeping the American dyestuff industry in a chaotic and confused condition and thus render it a fertile field for re-exploitation in the interests of the German dyestuff manufacturers when normal conditions are restored, is a question that should be carefully considered and guarded against.

"Whether it is feasible or not to establish a method of standardization on the outline suggested is entirely in the hands of you gentlemen to determine.

Registration of Samples.

"There is one thing, however, that can be accomplished. Such a Bureau of Standardization as might become one of the influential factors in the new dyestuff organization could effectively operate at least as a bureau of which I will call, for the want of a better term, registration. To it could be submitted types of the colors made by the American dyestuff makers as representing the standards which they propose to follow. These could be definitely tabulated and filed, and any consumer purchasing dyestuffs represented to be offered under the scale of standards adopted by the National Association would have the right to submit a sample of the delivery made for authoritative comparison with the original type standard as offered by the maker in the registry of the bureau. If the delivery should prove to be inferior to the type sample, it would be within the province of the Bureau of Standardization to call the attention of the manufacturer to that fact so that he might have an opportunity to correct his process and to make such allowance as would be proper to the consumer who had received the delivery, something which all reputable manufacturers would gladly seize an opportunity of doing. If, however, there should be a maker of dyestuffs who persistently made inferior deliveries and who refused to be bound by the original type deposited with the Bureau of Standardization, it would then be within the province of the National Association to expel such a maker from membership, and to cause him to lose his standard before the dyestuff consuming public.

Would Help Export Trade.

"This would in itself tend to eliminate the dishonest manufacturer and dealer, and it would overcome the evil from which the industry has suffered as regards inferior export deliveries which during the past year has done more to injure the reputation of American dyestuffs in foreign countries than any other one thing.

"It is suggested that a copyrighted name and insignia should be adopted which all members of the association in good standing shall be entitled to use on their letterheads, billheads, on their advertisements, or elsewhere, which shall be a badge of quality and which will so come to be regarded by the consumer.

"This is all that I need to say in the way of suggestion on the question of standardization, and I can safely leave it to you gentlemen to offer such suggestions as may occur to you, based on your own experience, with a view to devising some proper means for evolving a method of procedure which is universally recognized to be a desirable, and even an indispensable thing, with a view to the permanent establishment of our industry as an asset in American industrial life.

Arbitration.

"On the question of arbitration, this again is something which is essentially collateral to the question of standardization. Our courts have been congested with disputed cases during the past three years, practically all of them based on claims that deliveries have not equalled samples offered. In some cases these claims have been made in good faith; in others they have been just as evidently made in bad faith and in order to offset the conditions caused by a falling market or to obtain discounts to which the purchasers were not entitled. At present, the only way of adjusting these is through processes of law, and to this there is no limit of time or expense involved.

"If the two parties to a dispute see fit to voluntarily refer the question at issue to an authoritative central organization and to submit the respective merits of the dispute to this body with the knowledge that the claims will be quickly and authoritatively settled, a vast amount of time and expense will be saved, not only to the dyestuff dealer but to the consumer.

"Of course, this all predicates the establishment of a Bureau of Standardization under the aegis of the National Association which will be composed of business men and chemists who would be absolutely impartial and whose operations would be above suspicion and entirely confidential. It is not to be believed that such a body could not be organized from the ranks of the dyestuff industry; the outlook for the industry would be dark indeed if it should prove to be impossible.

Protection of Contracts.

"Another issue closely allied to the questions of standardization and arbitration of disputes is the one of the protection of contracts. The same body could very properly be invested with an adjudicating power as regards the protection of contracts. This is a question which is going to be of vital and widespread interest when conditions begin to attain normality, even if it has not become an active factor in the business as yet.

"In the panic-stricken times of 1915 and 1916, the color consuming industries were willing to sign contracts at almost any price, some of these contracts running for periods of two and three years from that date. Now a contract is not a contract unless it is equally binding on all parties thereto, and the difficulty is that a great many contracting parties only desire to be bound by a contract while it still operates in their favor. As soon as the market falls and prices range lower, they are apt to demand to be released altogether from the contract, or to have it adjusted so as to correspond with the new conditions. Where the manufacturer can do this without loss to himself by reason of his ability to buy his raw materials at lower cost, it is undoubtedly commercial wisdom for him to do so; where, however, the manufacturer has committed himself in good faith to other contracts on his part for raw materials, to which he is compelled to adhere, a breach of contract on the part of his customer at once works manifest injustice to him.

"If, therefore, there is a central authoritative board in which both the dyestuff manufacturers and the consumers have confidence, to which the merits of such a dispute as regards contracts could be submitted, shorn of endless litigation and limitless expense, it would be of unquestionable value to all parties, and its decisions, besides being rendered with reasonable promptness, would necessarily be based on commercial considerations of equity, rather than on the abstruse and mystifying construction of law.

The Tariff.

"One of the most important points for consideration by this convention is the question of an adequate degree of protection to be afforded to the industry by the United States Government. We have with us today representatives of the United States Tariff Commission, and Dr. Grinnell Jones will address us later, and give us some idea of the work that this Commission has already done, and proposes to do, to effect a tariff which shall insure the industry against extinction when the present disturbed conditions are past.

"Whether the present rates of 30 per cent. ad valorem and 5 cents per pound specific on finished dyestuffs and 15 cents ad valorem and 2½ cents per pound specific on intermediates is sufficient to enable the industry to meet post bellum competition is a question on which the United States Tariff Commission would like the expression of opinion of those engaged in the industry.

Unwise Features of Tariff Law.

"There are other features of the present tariff law as applying to dyestuffs which are unquestionably unwise, and are a menace to its permanent existence. I refer to the provision that after five years from the passage of the act in 1916, if the President should find that 60 per cent. of all the dyestuff requirements of the country were not made in the United States, he could arbitrarily by proclamation annul and cancel the specific rate of duty, and furthermore, that in any event after five years from the passage of the act, one-fifth of the specific rate shall be automatically dropped until at the end of another five-year period, the entire specific rate shall have been eliminated.

"How the estimation of whether 60 per cent. of the dyestuff requirements of the country shall be calculated involves a number of technical and intricate questions on which we shall doubtless hear something today, and into which I shall not go at this time. It is, however, clear that the existence of these stipulations does not tend to encourage the investment of the best and most permanent kind of capital. With the possibility of the wiping out of a large measure of the protection at present in effect, constantly in view, conservative capital looking for permanent investment will necessarily hesitate before committing itself to the support of the industry, and will leave the exploitation of the undertaking to the more undesirable and speculative kind of capital willing to take chances of quick and large returns during the period when such a condition exists.

Government Will Cooperate.

"The United States Tariff Commission has expressed the desire of co-operating closely with an authoritative trade organization representing the dyestuff industry as a whole, and I think we shall find that the representatives of the Commission who are with us today are quite prepared to give us all the encouragement we can expect that when the judgment of the trade is fully expressed, our interests will be safely guarded against unfair competition by those seeking to regain control of this market.

"The question of patents as affecting dyestuffs also is a matter of interest, and on this point also we shall have some information today from a gentleman who has made a close study of the question and is eminently qualified to speak on this subject.

"There will undoubtedly be other issues raised during this meeting which will, I hope, bring forth an exchange of opinion and which will be of benefit to our industry, but there is one question, not especially peculiar to our industry but which constitutes a distinct menace to our industrial life in many lines, on which I hope this convention will give some unmistakable expression of opinion—that of the use of bribery to effect sales, and to secure monopoly of control which otherwise would not be available. It has been distinctly and characteristically a German practice, and has prostituted the dyeing industry not only in this country but in all other industrial centres, Great Britain, France, Italy and Russia. It has been one of the insidious and pernicious methods by which the world-wide German domination of the dyestuff industry has been built up. While enlightened nations have been effecting legislation to eliminate unfair competition, it has eaten at the very root of the underlying idea, that of regulating the conditions of trade so that the small merchant may have an equal right of existence and to the profitable continuance of his business as the large merchant. It has been a festering sore, the more dangerous in that it has necessarily been secret and unseen, which calls for a drastic and ruthless application of the knife.

Must Take Firm Stand.

"It is not amenable to defence, and the only reasons for its continued existence are that there are some influences which see their own self-interest involved in its retention, or that we are too timid to recognize its existence and to take a firm stand on the side of right and justice. In that it cancels the reward of merit and frustrates the rightful development of true progress, it is unfair, unmoral and un-American, and the influence of this proposed association cannot be exrcised in any more righteous direction than in the destruction of this baneful disease which has been imposed on our industrial body.

"This, gentlemen, is a brief outline of the ideas which have actuated the calling of this convention, and I commend them to you with all reservation, and as being simply an individual expression of opinion, believing that the exercise of your good sense and business intelligence will work out a line of development which will make our new industry, created so successfully, and with such unparalleled promptness, a permanent and valuable asset of our industrial life, with the interests of all, both large and small, and whether manufacturer or dealer, properly and fairly considered and safeguarded against unfair discrimination and competition from any source either inside or outside our own ranks."

"If we are to take Mr. McKerrow's address step by step we would have to have a five day convention," declared Mr. Hemingway. "In view of the fact that our program itself provides plenty for the short time at our disposal I shall not make any introductory remarks except that I want to say in regard to the item on the program that the gentlemen who came together to talk over the general arrangements for this meeting today were a little at sea as to how to proceed, as to what arrangements to make toward a charter and by-laws, should you form an association. We were fortunate in getting Mr. Benjamin H. Kaye to help us. Mr. Kaye has had experience in this sort of work and has devoted several days of his time to lining up the general form of the association for us."

MR. KAYE ON ORGANIZATION.

"Mr. Hemingway has in a measure explained why I am here, but briefly the problem of association work is one that is always interesting to me. When Mr. Hemingway called me up and asked me if I could give a little time to the gentlemen who were interested in forming the association and I came up and attended the meetings, I heard the same line of complaints which I had heard in the other industries. There was the same talk of trade jealousies, mutual distrust. We had the same thing in the leather industry, we had in some degree the same thing in the disinfectant industry and yet a short time after the association was formed all those things were swept aside.

Success of Other Associations.

"One of the gentlemen at the meetings I attended last week scoffed at association work and said there are not many associations going anyhow. I have before me a report of the Department of Commerce on Commercial Organization, published in 1915, which gives five hundred national associations, aside from state associations and local associations. They cover practically every branch of industry with the exception of the dyestuff industry. I do not want to take time to summarize these associations because I take it for granted that by your attendance you are interested in association work.

"I have an illustration that may have some weight with you. When we formed the Disinfectant Association, we found a very strong distrust among a few of our Western people against the West Disinfecting Company. That is a very able organization with a well-established laboratory and well committed to the doctrine of the standardization of disinfectants. Some of our members took me aside and warned me against the West people. One of our members, after one year, who had been most outspoken against the West people came and asked me if I would seat him next to Mr. X. of the West Disinfecting Co. It was a case of two men who had had an opportunity in that year of sizing each other up and finding out what each other stood for and finally realizing that by standing together they were doing each other the most good and not harm.

Case of Dye Industry Urgent.

"If you come together you are going to find the same spirit in your entire industry, and, as Mr. Hemingway has said, great good will be accomplished by coming together and seeing and knowing each other and realizing that you are all members of a large association and that, while each man is determined to make his way in his business, he can best do that by co-operative effort with other men in the same industry.

"When the dyestuff matter was put before me I began to realize that of all the industries in this country the one that stood in most need of associated effort was the dyestuff industry. Not merely because it is a new organization, just starting, but because of the things which you will have to meet. Of course prominent in all our minds is the idea of German competition, and there, genelemen, you are meeting organized competition of the most potent type. Organized not merely in brains, but organized in government control and in activity, and, just as no single nation could stand up against Germany in the present war, no single manufacturer is going to stand up against German competition in the war for trade supremacy.

Insidious Propaganda.

"They are too well organized for that and you must organize to meet them. Their propaganda work is not only carefully planned, remarkably backed both financially and by brains, but also insidious in its workings. We know that they have practically government backing and government control. There are six leading German companies and seven smaller German companies. But theirs is an organization, and I am informed by Mr. McKerrow that there are already today in this country something like 130 manufacturers of dyestuffs. On the face of it, how is the disorganized effort of 130 concerns going to meet the organized effort of thirteen huge, active and well-established concerns?

"Then again you have the competition of the other nations, England, Switzerland, Sweden, Italy, Japan, all of them making a strong effort to get their hands into the dyestuff industry. It is only by associated effort that you are going to accomplish the saving of your own industry, not merely by the interchange of thought, but by government protection.

Obtaining Government Support.

"No single concern in this country can go down to Washington and have proper legislation passed to protect this industry. Apart from the difficulty of obtaining government support when it is suggested by one concern, you have the constant distrust at Washington that some individual concern is planning something for its own benefit, and even if you gentlemen were not aware of an effort being made, some Congressman or some Senator will ascertain that a bill has been pressed and backed by a certain concern and immediately everything is in confusion. But when you go to Washington as an association representing the entire industry, you receive the most courteous attention, a fair hearing and usually you accomplish your result.

Killing Ill-Advised Legislation.

"In the Disinfectant Association we received word that a bill had been railroaded through the Connecticut legislature providing for the putting of a final co-efficient number on all disinfectants. That is one of the steps toward standardization of disinfectants. Three years ago the members of the Association were opposed to that standardization, today they are in favor of it but realize the difficulties of establishing a definite standard. The bill as passed was very badly drawn. We were not opposed to the establishment of a final co-efficient law in Connecticut; we were opposed to putting a statute upon the books which would demoralize the industry.

"I got in touch with the sponsor for the bill and arranged to meet him. We met on the train; he, the man who proposed the bill, Mr. F. Walker, one of our members who discovered the bill, and myself. We took a compartment on the train and by the time we reached Hartford we had re-drafted the bill for him, with the result that though the bill had already passed both houses, it was withdrawn, and the bill which had been drawn by us was passed in its place. And today, while I realize it is not a perfect bill, it certainly covers the point infinitely better than the original one.

Application to the Dye Industry.

"The same thing will apply to you with the dyestuff industry. If it is a question of tariff changes; if it is a question of getting the government to see how closely you are allied with the munition industry, you will get a hearing as a body and not as an individual. I pointed out to the gentlemen of the committee that we must proceed very slowly, that it lay not in the power of a few men meeting last week, or in your power, in a quick and arbitrary manner to adopt a form of arbitration or a definite plan of propaganda work. An association is formed very much in the manner of the formation of the United States of America. There were a lot of colonies and they got together in 1776 and declared their independence, and then in 1776 they discussed Articles of Confederation, and from June, 1776, until February, 1781, these Articles of Confederation were first discussed and then gradually submitted to the various colonies for adoption. The Constitution of the United States was not adopted until 1787.

Method of Procedure.

"You must do about the same thing here. You are meeting not to declare your independence but your inter-dependence. Every man is privileged to get up and explain what his company does, and we want him to do it. The views of all the gentlemen present taken together and read over will form the body of thought upon which your organization committee will be enabled to work. I suggested to the meeting last week that your procedure should be a similar one to that of any other organization.

"At the meeting today, if possible before the close of your morning session, have your chairman appoint an organization committee, this committee to be limited to merely making out a statement of the purpose of your organization and a general plan of procedure. Then have your committee empowered to act as an organization committee only until your first annual meeting and by first annual meeting I do not mean a meeting a year from now but a meeting two or three months from now.

"During that interim your committee will be empowered to entertain and pass upon applications for membership. It will be in a position to consider the various topics of bylaws, etc., the question of classification of membership, dues, propositions for propaganda work, etc. And I also suggest that the Chairman of the organization Committee arrange for a series of committees selected from the manufacturers, on the various topics which have been discussed and will be discussed, such as registration of dyestuffs, standardization, arbitration of disputes, patent law, trade revision, propaganda work, and each one devoted to its own topic, and in the interval between this meeting and your first annual meeting, can lay the data upon which it may render a comprehensive and intelligent report. Upon the reports so rendered you can establish what will amount to your constitution, the principles for which the association will definitely stand.

"These are practically the only suggestions I want to lay before you. I desire if you have an organization committee appointed to have the opportunity of meeting with and advising with them and give them the benefit of whatever experience I have had.

Urges Against Delay.

"I just want to leave you one thought. No manufacturer in this country, especially in this industry, is big enough to dominate the United States in its legislative policy; nor is it big enough to dominate this industry. But if you keep on going ahead in your line, as 130 separate concerns, as soon as the war is over and your real competition commences, one by one you are going back to the wall. This is the time for you to form your association and not wait until the enemy is within your borders. We have learned our lesson in preparedness and having learned that lesson, I suggest that we prepare now."

ORGANIZATION DISCUSSED.

Following Mr. Kaye's address, which was well received, the dominating topic of the day, that of organization, was then brought to the fore when Mr. Hemingway announced a general discussion on this subject. After a few scattered remarks and suggestions from various parts of the hall, L. A. Ault, of Ault & Wiborg, Cincinnati, Ohio, precipitated a lively discussion when he gave utterance to an angle of the subject which evidently lay close to the hearts of all.

"It seems to me," declared Mr. Ault, "that this should be an association of manufacturers only. I should be pleased to hear what the gentlemen who discussed this convention last week think of it."

Dealers Want Place in Sun.

Chairman Hemingway said it was his understanding that the association was to be one of manufacturers and dealers in dyestuffs.

A dealer present stated his belief that it was in the minds of all that the prospective organization should be a commercial association that would bring in responsible manufacturers and dealers in dyestuffs and intermediates, and would include such dyestuffs as alizarin, turkey red oil, etc.

Elvin H. Killheffer declared, "I think manufacturers are in sympathy with Mr. Ault. Is this a meeting of manufacturers or a meeting of dealers? I think it is the feeling of many of the former that manufacturers and dealers have nothing in common. While it might be a commercial association in which the dealers might be a subsidiary part, there are a great many subjects which must properly be decided by those who actually make the dyestuffs."

Difficulty Was Foreseen.

This was evidently the solution which had been in the minds of those who planned the convention, for Chairman Hemingway declared that at the preliminary meetings, held the week previous, the feeling had been that when the organization committee was formed it would be composed largely of manufacturers, who would give their first thought to the question raised by Mr. Ault.

"It was felt," he continued, "that the final decision would be in favor of two classes of membership; Class A for manufacturers, and an associate membership for dealers. I do not wish to speak in advance, or suggest what the committee shall do, because the committee will be chosen from among you, but that. I think, is the big thing for you to decide."

Manufacturers Important, Says Dr. Matthews.

Dr. Matthews was emphatic in his belief that the organization should be primarily an organization of manufacturers.

"I had the privilege of sitting in at this meeting." said Dr. Matthews, "and the thought in the minds of these people, I believe, was that the problems which would arise in this association were chiefly manufacturers' problems, and consequently that the manufacturers had certain interests which probably were not associated directly with the dealer and with the consumer. Sensing the attitude in the minds of those representing the large manufacturers. I came to the conclusion that this organization, if going to be backed by the manufacturers, either large or small, would necessarily emphasize the manufacturing end of it.

"As you know, we discussed the probability of bringing forward the idea of two classes of membership. active and associate membership. The active members could consist of those who were actually manufacturers of dyestuffs, and the associate members should represent those who were interested in the allied trades, such as in the selling of dyestuffs, the manufacturing of machinery for use in dyestuff manufacture, etc.

"It might be patterned somewhat after the National Cotton Manufacturers' Association and various other trade organizations. If this is to be a trade organization, it has got to hold forward the idea that it represents the trade as a whole on related and unrelated problems.

"The idea that we had in view was that the emphasis should be laid on the manufacturers. That is the opinion. I think, of the principal manufacturers of dyestuffs, and an organization that would leave out the principal manufacturers of dyestuffs I do not think will get very far in developing the industry. We had a strong note of Americanism. It is in its infancy now, and has not yet grown to the vast proportions which many people abroad think it has. It needs care and guidance.

"There are many problems regarding manufacturing which this organization can handle: the relation to the Tariff Commission, the distribution of raw materials for the manufacture of dyestuffs, etc., the say-so as to who shall use this or that or the other thing. If that matter is unrelated and not harmonized by any organization which will co-operate among the different manufacturers to settle questions as to who will get this and who will get that, the small manufacturer will be left out and the big manufacturer will get more than he really should have. The thing is that the organization should be primarily an organization of manufacturers.

Why English Failed to Organize.

"If you will refer back to the dyestuff industry in England," continued Dr. Matthews, "you will find that there were a lot of broken-up efforts toward making dyestuffs, and what was the result? It died a natural death because of the lack of co-operation in dealing with manufacturers' problems. When the Germans took hold, they started to organize and co-operate. The number of manufacturers has narrowed down to a small number, and by their size and co-operation they can do things which a lot of disorganized manufacturers cannot do.

"We are at the same place as when England first started. We have a hundred or more manufacturers. People are duplicating their efforts. losing a lot of energy and capital through not co-ordinating their experience, capital or efforts. If we do not do something toward co-ordination, when the war stops and normal conditions return. we will be up against a strong organization. I think that in the minds of those who acted in this little committee was the thought that the problem was a manufacturing problem primarily.

Must Agree or Fail.

"Now, if this convention takes and runs away on the other side, I am afraid that the effort will be in vain: that the large manufacturers, or what you might term the bona fide manufacturers. will look with askance at an organization that will not deal with manufacturing problems, but will deal with commercial problems."

Dividing Line Hazy, Says Dr. Pierce.

Dr. Pierce wanted to know just how the two proposed classes of members should be separated. "There is no sharp dividing line between dealers and manufacturers," he said. "Would you exclude the manufacturers who made twenty-five colors and also made some glue as a by-product? If there was a small factory which made two colors, and likewise bought and sold dyes, they would be a manufacturer in one sense of the word, and some of the large manufacturers would be dealers."

Mr. Chapin suggested that this might be determined by the arbitrary selection of a certain number of standard products, and then passing a rule that all manufacturers must prove that they are making this number of colors before they could be classed as manufacturers.

Manufacturers Only, Thinks L. A. Ault.

Pursuing his original subject, Mr. Ault said: "I would like to call this to your attention: What is the opinion of the dealer worth, compared with that of the manufacturer? He has no interest in the manufacturer. I cannot conceive why I should get sympathy or worry because of lack of sympathy from a dealer. The dealer buys his goods anywhere he pleases, and is not interested in the welfare of any particular manufacturer. A man should be a manufacturer—or he should not be in the organization."

Considerable stir followed this remark, and it was not until Mr. Kaye quoted Mr. Poucher, of the Du Pont Company, as being in favor of recognizing the interests of dealers, that the heated controversy was finally lulled. According to Mr. Kaye, the Du Pont representative expressed himself as follows:

"Our one underlying idea is to keep the manufacture of dyestuffs in America. The dealer has this interest in common with the manufacturer. Another important point to remember is that if you went down to Washington in an endeavor to have legislation passed, you would probably get more consideration if you represented 700 firms instead of only 100."

Dealers Withdraw Temporarily.

Seeing that the chances of an amicable agreement were apparently as far away as ever, B. P. Donnelly, of the Holland Aniline Co., Holland, Mich., came to the rescue with the suggestion that the two interests hold separate meetings to talk things over by themselves. The opportunity was eagerly grasped, and after a census revealed that the dealers present were greatly in the minority, they withdrew from the hall to meet in another room in the building, leaving the manufacturers in full possession of the field.

Status of Foreign Interests.

Before taking up the question of the dealers' status, the manufacturers, after the doors were closed, considered the attitude which should be taken with regard to foreign manufacturers of dyestuffs. As a corollary to this, Dr. I. V. Stanley Stanislaus, president of the Stanley Aniline & Chemical Works, Lockhaven, Pa., thought that the status of American manufacturers located in America, and owned by foreign interests, should also be decided.

A. Brooking Davis averred that some foreign manufacturers have larger interests than the domestic. "Why should they be excluded from this organization?" he queried. "Their co-operation would be valuable."

Other matters for consideration brought forward were plants controlled by American interests but having an intrest in the country of an alien enemy, and American manufacturers with foreign agencies.

Favor Pan-American Organization.

The general sentiment, however, seemed to be in favor of making the organization Pan-American as to membership, with possible relations with foreign organizations of a similar character whenever it might seem advantageous; and also to make the bona fide manufacturers the foundaton and principal substance of the organization. Put into concrete form, these decisions were finally presented to the meeting of manufacturers as resolutions, which were unanimously passed in the following form:

> RESOLVED: That there be organized an American Association of Dyestuff Manufacturers, composed of American manufacturers of dyestuffs, financed with American money and located in America, for the protection of the American industry of the future, and be it further
>
> RESOLVED: That this organization shall consist of two classes of membership; active members, who will have voting privileges and shall consist of manufacturers of dyestuffs and intermediates; and associate members, who shall not have a vote, and who shall consist of dealers or distributors, or manufacturers of co-related products used in the dyestuff industry.

Mr. McKerrow in Role of Hermes.

Following the enthusiastic passing of these resolutions, Mr. McKerrow was delegated to convey the decision regarding membership to the dealers' body meeting in separate session.

David W. Jayne, of the Barrett Company, then expressed his hope that the new organization might become a part of the Chemical Alliance, which was formerly the Chemical Committee of the Council of National Defense formed shortly after the outbreak of the war.

JAYNE ON CHEMICAL ALLIANCE.

"If you have a broad organization of dyestuff manufacturers you are going to be interested in the so-called Chemical Alliance," declared Mr. Jayne. "The Council of National Defence appointed a lot of advisory committees last spring, one being the Chemical Committee, expected to do a certain piece of work, but being merely a committee it could not handle it, and therefore they organized and incorporated the Chemical Alliance. This fall, when the Council's committees were put out of existence, the Chemical Alliance was brought forward as a substitute for the Chemical Committee of the

Council. They did not want the chemical industry disintegrated. There had been some very good results from cooperation with manufacturers, and anything that you could suggest as an organization to keep the chemical trade together will be of advantage to the nation.

"We put forward this Chemical Alliance as a solution of the problem. It is constituted of sections of the chemical industry and at the present time we have the following sections: Acids, coal-tar by-products, foreign pyrites, fertilizers, alkalis, domestic pyrites, sulfur, etc.

Dyestuffs Should Be Represented.

"I feel that the dyestuff manufacturers ought to be represented by a section in this Alliance, and at the December meeting I got permission to approach the dyestuff trade and see if it would not join the Chemical Alliance.

"I hope that we are going to get a dyestuff section of the Chemical Alliance. The principal point regarding membership is that you must be a manufacturer in that section. Dealers are not considered ordinarily in government cooperation, and I think that it is a thing which every dyestuff manufacturer, as a user of all these other chemicals, must certainly be interested in.

"You can easily see that every dyestuff manufacturer uses acids, alkalis, etc., and being associated in the Chemical Alliance must bring you more in contact and enable you to present your requirements to the government in connection with the well-known situation in acids and alkalis, much more satisfactorily than if you were an outside group, and I think that all of the members ought to belong to the Chemical Alliance."

Dealers Want Further Parley.

Scarcely had Mr. Jayne concluded his remarks when, amid an expectant hush, Mr. McKerrow returned from his conference with the dealers. He said that he had reported the manufacturers' decision to the dealers.

"But they feel that there are certain aspects of this question," he announced, "which have not been gone into as fully and fairly as they should be, and they suggest that you appoint a small committee from your number to meet a small committee from their number to discuss these matters and report back to the convention later."

Dr. Matthews, Mr. Merz and Mr. Ault were thereupon appointed to confer with the dealers' committee, consisting of Mr. Webster, Mr. Hollywood and Mr. Beatty, and the session was adjourned for the morning.

DR. PIERCE ON STANDARDIZATION.

The afternoon session opened with the two committees still in conference. The first address scheduled was that of Dr. Edward Wallace Pierce, of the U. S. Conditioning and Testing Laboratories, New York, and proved to be one of the most important contributions to the convention. Dr. Pierce spoke on the question of dye standardization, which he declared to be perfectly feasible, and proceeded to show just how this problem might be approached.

Ultra Violet Color Testing.

He called attention to the excellent results obtained through the use of ultra violet light for color testing and explained the advantages of this method over the use of sunlight from the standpoint of time-saving and uniformity. He also told of the activities of the U. S. Bureau of Standards, and urged that the manufacturers take speedy action towards establishing a standard in order to forestall the inevitable and possibly more drastic regulation from Washington. Dr. Pierce's address, together with several interpolations, follows in full:

"A form of standardization is possible and is being applied at the present time," said the speaker. "All that needs to be done is to adapt it to the needs of this association. I have prepared a few remarks on the subject.

"While the majority of events which have culminated in this convention have had their inception since the beginning of the war, this question of testing and standardization goes back to the very origin of coal-tar dyestuffs. It is now over twenty years since I first began testing, classifying and attempting to standardize dyes, and with your permission I will try to outline the difficulties and possibilities, in order to see whether we cannot, at this time, take steps to adopt some uniform system that will, at the same time, be acceptable to both consumer and producer.

How Germany Maintained Standards.

"Before the war, all my work was done in the interest of a branch office of what was then, and is now, the largest American dyestuff factory. No one who had not been through the ordeal could picture the difficulties of holding out against the German competition of those days, but it can be readily understood that business was only possible by being able to supply goods of as high quality and rendering as efficient service as our foreign competitors. The standards of those days were set by the large German factories, and it is said that there was between them a free interchange of type samples in order to maintain a certain uniformity in shade and strength of dyes made in the various plants. These standards were created arbitrarily, as we see in the case of such dyes as Rhodamine-B, which was only 20% of its full strength; Chrysophenine, which was 40%; Chinoline yellow 20%; Auramine II 33 1/3% of Auramine O, which, in turn, was 75% less than the pure dye. The list might be prolonged to great length, but the facts are generally known.

Samples Must Not Be Best Quality.

"Now it is not only permissible, but an actual necessity, for a factory to have a sample for commercial purposes which is somewhat below its best possible production; otherwise it would be burdened with large quantities of dye below standard, because no factory, no matter how high its efficiency, can turn out every lot perfect. This point will always be insisted upon by the manufacturers and conceded by the consumers. A second class arises in cases where the factory batch is not simply below strength, but is off shade and requires some other dye to be added to bring it to type shade. A third class is deficient in brilliancy or solubility and can never be made right by mixing other color with it. These manufacturing problems are the cause of all the arguments concerning standardization. Of course we must consider deliberate adulterations and substitutes, but as these are so easy to detect they constitute no real problem.

"Every factory worthy of the name maintains its testing department, and is fully aware of the deficiencies in each lot of dye produced. Corrections are made and the lot brought up to the factory standard if possible. Extra strong batches are mixed with weak ones and different off-shades are mixed to correct each other, outside colors only being added when there is no other remedy.

Some Testing Methods Employed.

"The methods of testing dyes are generally known to chemists who have specialized in such work, but, unfortunately, there has been no definite rule, and each operator uses whatever methods he deems best. In the case of comparison of two samples of identically the same dye we may use a colorimetric method. In all such tests equal quantities of the dyes are dissolved in equal quantities of water and the relative depths of color of the solutions measured either in Nessler jars or cylinders, or more accurately in a colorimeter of the Campbell-Hurley type, and for very exact work in the Kobel colorimeter. Whether the two samples are identical in composition or not can be determined quickly and accurately by observation through a small direct-vision spectroscope and the identity of any other additions established by consulting the tables compiled by Formanek.

"I have been criticized for using the colorimetric test. There is one drawback about the colorimetric method which is also a drawback about others. No attention is paid to the amount of mixture present.

"If the two dyes are not of absolutely the same nature, the colorimetric test is of no value and we must depend on comparative dye tests. In the comparative dye test it is always essential that both dyes be applied in their proper manner under exactly the same conditions. Slight differences of time, strength of both, temperature, etc., have great influence on the value of the test. Samples dyed at different times are never to be considered as comparative. While the colorimetric methods are accurate within 2% or less, the comparative dyeing is not effective for differences of less than 5%. This is due principally to the inability of the eye to distinguish on dyed fabrics as closely as in the instruments.

Ultra Violet Rays for Dye Testing.

"The means of testing for mixtures and the material used for reduction are simple operations, and by the use of the microscope can be made to give dependable results. The methods of testing for fastness to different influences are more varied, and while the U. S. Government has specifications for dyed materials, there needs to be an American series of tests that will be uniform.

"The Government demands that a sample shall stand thirty days' exposure to the sun. In July, when you have clear days every day, it is one thing, but thirty days' exposure to the sun in January and February is an entirely different thing. And the goods must always stand up as well as a certain sample which the Government will supply. We are bringing forward the ultra violet test for dyes, giving them forty-eight hours' exposure to the ultra violet light. Sometimes slightly different changes take place in colors that do not take place in the sunlight.

"The ultra violet lamp has been extensively used for tests for fastness to light, but at present we need a scale of fastness that will mean more than the terms used at present—one that will express in hours or days how long any given percentage of dye will resist. This can be done, and, whether this association endorses such work or not, it will be carried on independently.

"The ultra violet light gives off an assortment of rays. Some of them are invisible. The action of ultra violet light, as soon as the apparatus is started, is indicated by the smell of ozone in the air. There is only one way to bleach linen properly; spread it out on the grass, sprinkle it with water and expose it to the sun. That is not an ultra violet action. It is a genuine oxidation of the coloring matter of the fibre. This is the difference between sunlight and ultra violet exposure. There is no moisture present in ultra violet exposure. When we say a color is fast, moderately fast, very fast, or not fast, we are able to express that it will stand a certain number of hours' exposure without changing.

What Dye Standardization Means.

"Standardization is one of the burning questions before this meeting. On it hinges the question of whether certain producers will join or stay out. There seems to be a slight misconception of the meaning of the word. A recent article by Mr. McKerrow spoke of the standardization of the names of colors so that we would have a rigid arbitrary shade to represent each fancy color and a universal use of such standards. This very thing has been most admirably covered by the Textile Color Card Association, and while most useful and commendable, is an entirely different problem from the one before us.

Will Please Consumers of Dyes.

"A standard is not an ideal—it is a unit or system of measurement. Before the war, the German factories had standards of their own making, and today we can have American standards of our own making. We already know how to measure and appraise these goods. We want every manufacturer to make for himself a type or standard of each of his dyes and put these on record, as it were, by depositing samples in the hands of a dependable custodian. From these samples portions can be issued to those interested in testing, and the manufacturer will obligate himself to make deliveries equal to the type he himself established. Probably when several factories are making the same dye, it will be possible to bring about a uniform standard between them which will really be a great convenience to those you must seek to please—your customers. This will work no hardship nor restriction on anyone, except on the manufacturer who delivers second-grade goods when he has agreed to furnish first-grade.

"No honest manufacturer has anything to fear from such supervision, and further, if it is not done voluntarily by this association, it will be done by other and more critical authorities.

U. S. Bureau of Standards Already at Work.

"The Bureau of Standards, at the instigation of the Federal Trade Commission, is at work along such lines at the present time. The institution I have the honor to represent is doing this work now in the interests of consumer, dealer, exporter, or whoever desires to know the truth. Our success has been partly due to the fact that, on account of such long association with the selling end of the dye business, there is not that danger of my taking the narrow-minded view that characterizes the reformer or purely scientific investigator. Your troubles are known and your critics and competitors are known, so that our efforts are always toward effecting a better understanding rather than fostering a controversy.

Forestall Future Foreign Competition.

"These things are quite possible under your own supervision and thereby you can forestall the more severe supervision of Washington. The only obstacle that can be foreseen is the disinclination of certain manufacturers to obligate themselves to make uniform deliveries. This is a measure of preparedness for the competition which is to follow the war. Before the war the Germans set the pace for us to follow—let us set up a standard of our own and insist on clean, open business methods, and defeat their effort to get this businass away from us again."

CHAPIN ON BY-PRODUCTS.

Dr. Pierce was followed by Mr. Chapin, who pointed out the conservation which could be brought about through co-operation in the sale of by-products resulting from the manufacture of dyestuffs.

"I have two subjects that came into my mind that have not yet been presented—two subjects which I think could rightly form the scope of a dyestuff association. The first is the matter of preventing needless duplication of effort.

Needless Duplication of Effort.

"In my work as consulting chemist for the trade, I have become more or less familiar with the colors that are being manufactured, and of the needs of the trade, and I find a great many similar colors being produced by numerous concerns. It has occurred to me that one of the intentions of this association might be to act as a sort of medium by which the field could be divided up.

"There are many dyestuffs which are most difficult to make, that are needed by the trade, and needed very badly. I was talking with the purchasing agent of a large mill recently and he said, 'I have had hundreds of such colors as fast red, etc., but it is impossible for me to get certain colors which I need in my business,' and I think that this has been and is the condition which we face, and an exact report by such an association could act as a means by which different concerns could be helped and steered to certain fields in which their efforts would lead to the best result.

Utilization of By-Products.

"There is another point which has come to my mind, and that is that such an association could act as a means for the utilization of by-products. As you know, the dyestuff industry produces a host of by-products. You may be making one color and getting a by-product which could be worked up with more apparatus. This by-product piles up, and if one can find a market for it, it is an added source of revenue, and it frequently happens that such a by-product may be the raw material that somebody needs.

"These are the two aspects which have appealed to me very strongly because I think they are two features which, if worked out, would react to the good of the industry in this country."

Agreement on Membership Reached.

The joint committees of manufacturers and dealers then returned to the hall, and Dr. Matthews, who acted as their spokesman, reported that a full agreement had been reached. The decision differed from the original resolution passed by the manufacturers in that it provided that the dealers should have a representative in the governing body of the association and that the admission of any firm to associate membership should be passed upon by a committee consisting solely of associate members.

Dr. Matthews' words were:

"The committee has come to the understanding that: There are to be two classes of members: first.

the active members, consisting of dyestuff manufacturers who will be those who are entitled to vote; second, a class of associate members, the dealers and makers of machinery or other allied industries.

"That the associate members are to have a representative on the Board of Governors, or Executive Committee, or whatever that committee may be which will direct the business affairs of the organization.

"Secondly, that the membership qualifications of associate members be determined by a committee of associate members. The associate members feel that their membership should be scrutinized by them. Associate members are to be properly represented on arbitration."

Vote to Organize.

These revised terms were received with enthusiastic applause, and without further ado Mr. McKerrow put the motion for organization on the grounds just stated, which was promptly seconded by Dr. Stanislaus and, amid additional applause, was passed unanimously.

This closed all discussion for the day, and the Organization Committee, headed by Dr. Matthews and consisting of Messrs. McKerrow, Ault, Merz, Woodward, Hyndeman and David, was appointed to effect the details of organization. The balance of the afternoon session was spent in listening to the addresses of Dr. Matthews, Albert E. Parker and Bradford Webster, which follow.

DR. MATTHEWS' ADDRESS.

"What objects this organization has, I think, have been pretty well brought forward in our preliminary discussion. The main idea is that we shall establish and maintain a dyestuff industry in America. That is the proposition we must always keep before us.

Time Not Ripe for Increased Duty.

"As to the objects secondary to that, we have many and diverse ones. First, the relations of the industry with the Government, particularly in regard to the tariff law. As you know, we have already a dyestuff tariff, seen through very largely by the consumers of dyestuff in this country. I do not know of any other example in tariff legislation that showed a condition of affairs where the consumer of the product stood back of the manufacturer and helped to get legislation through. We have to consider that bill as it stands. Those familiar with the present tariff bill know that it has certain incongruities and certain obstacles which should be met in the proper interpretation and carrying out of that bill. Unless these obstacles are taken out, the tariff bill will not come up to the expectations that we have entertained. The Tariff Commission which has been appointed to deal with tariff problems is working on this proposition, and as I understand it, they are waiting for us as an organization to formulate something in connection with their own ideas and with their own work, so that a just and equitable solution of these obstacles may be made. One of the first things to go up before this organization is the question of a proper representative committee which will study out this tariff proposition and meet with the Tariff Commission and give it the needed co-operation and aid. I do not feel at the present time that we are justified in yelling for a higher rate tariff.

"Suppose we take the bill as it stands and try to justify it by smoothing out the obstacles. Probably a new bill will have to be drafted in order to do this. But it should not be our purpose to bring forward our selfish ends. Let us take the tariff rates as they stand and try to co-operate with the Government and with the Tariff Commission, in order to make that bill a proper working basis, and something which will be of benefit to us and to the Government.

Should Cooperate with Government.

"In the second place we have our relations with the Government at the present time, which is very important. As you know, the Government is controlling the raw materials; for instance, it is distributing these materials on the basis of war conditions, and the dyestuff manufacturer needs many of these materials to carry on his business. This question should not be gone into in a selfish way. We should realize that our Government has certain needs and that we must sacrifice if it comes to a show-down. We should have a committee which should co-operate with the Government in the distribution of raw material.

"Because the Government officials are not always well educated into just what materials are needed, we should have a committee which should deal with these problems in a spirit of patriotism and consider the ends of the Government as well as the manufacturers.

Unfair Competition.

"In the third place we have another relation to the Government and that is in the question of unfair competition. As you know, we have a variety of laws on unfair competition. The dyestuff industry should start out right, and start out with an ideal ahead of it that is going to eliminate unfair competition. We have had it in the manner in which the German houses did business over here. In some cases the dyestuff business was looked upon with askance. The men in the dyestuff business were supposed to be highbinders and grafters.

"We want clean business if we want any at all, and I think it is American principle to have a clean business. We do not want to do anything that is not proper, equitable and just in a business sense. Nothing shall creep into it that is not truly American in spirit and clean in business methods. Otherwise we are bound to clash with the Government.

Some Causes of Disputes.

"Now we have other things in view, unrelated to the Government but related to the community, and this brings us to the question of the amicable settle-ment of disputes. Probably there are a great many just causes of dispute from buyers of dyestuffs and consumers who do not always watch the material they buy as closely as they should. As a general proposition you might think that people buy mostly by sample and if delivery is not up to the sample it should be rejected. There are many points which come into play which do not show on the surface. The manufacturer or dealer may be perfectly square and the consumer may be equally square, but the object of an arbitration board would be to study these problems intelligently in order to arrive at a just judgment. There are many problems coming up relating to manufacturer and consumer which can be dealt with by arbitration without going to a law court.

Good Fellowship.

"There are other things with regard to our relation to the community, and one is the relation to our good fellowship toward each other. Most organizations of this type build a great deal on the power of good fellowship. If everybody goes into his own corner we will have jealousies which work to the destruction of the business rather than to the upbuilding. You cannot be an enemy very well with a man you can sit down and chat with, and take dinner or smoke a cigar with, and these things will help a great deal in the smoothing out of many difficulties. Sit down face to face with a man and discuss a thing, and many of the great objections will melt away and we will get the same point of agreement as we did with our meeting of the committee. All this will make for a benefit to the trade.

Why Manufacturers Should Control.

"The reason the manufacturers have emphasized their controlling end of the affair was not a question of lack of co-operation with the dealer, but was based upon an economic principle. The problems which this organization has to deal with are chiefly manufacturers' problems. It is not a question of not being in sympathy with or co-operating with the dealer, or with the other allied industries; it is rather a question of the business end of the organization being conducted by those who know the technical requirements and the technical points, and they have the knowledge to meet the various problems which arise, and it would have been foolish to have an organization of this character start without the co-operation, without the support, of the dyestuff manufacturers. It would have been a mere shell and would not have gotten anywhere. I think in the little report we have made on this matter that we have been probably as fair as possible in meeting the requirements both of the dealer and the manufacturer.

"As to the personal features of any manufacturer's business, I do not think it is the business of this organization, or of any organization of dealers, to interfere with a man's business. We can only deal with those problems which affect the industry as a whole. And if the question comes up, for instance, of the selling of dyestuffs by one person to another, it is none of our business whether Mr. A. wants to sell to Mr. B., or not. But if some broad proposition comes up which affects the whole industry, like the tariff question, or the formation of associations, the distribution of raw materials through the industry as a whole, why then, unless we have complete co-operation, we will not get any great benefits in pushing this to the front."

ALBERT E. PARKER ON PATENTS.

"The American patent situation is commented on in the annual financial review of a leading New York banker as follows," said Mr. Parker.

> "'The miraculous growth of a great commercial industry should not be overlooked. Since the war $320,000,000 were invested in new chemical ventures in this country. A considerable part of this sum was for the manufacture of explosives, but much of it has been applied to chemical and dye plants, which will become a prominent factor in American industry. This industry means another big loss to Germany and has still to face a critical period when calm conditions return. German competition in dyes after the war will unquestionably be severe, and probably Congress will be asked to grant help to the industry.'

"For more than two and a half years before the United States entered the war American manufacturers in all lines of industry were placed in a disadvantageous position in the matter of the use of many important inventions in the industries concerned, as compared with the citizens or subjects of the countries with which we are now allied, by reason of the fact that after the war commenced in 1914 most of the European nations passed legislation under which the manufacturers in those countries could secure licenses at low royalties for the use of inventions which had been successful in enemy countries, but which by reason of the war could no longer be used in the countries of our Allies, due to the fact that they were owned by the enemy.

"The legislation which was passed in 1914 permitted the use of these inventions so as to bring about the continued supply of the product, and the manufacturers therefore were able to fill practically all the needs for articles which had formerly been imported or which in some cases had been manufactured in these countries after payment of substantial royalties to foreign patentees.

"Many reports were circulated that all patents owned by enemies in Great Britain were to be confiscated for the benefit of British manufacturers and it was freely stated that English manufacturers might then be free to make any article in Great Britain covered by enemy patents with sanction and authority and without payment of any consideration for that which was to be manufactured.

No Truth in Statement.

"There was no shadow of truth to this statement, which action would, of course, amount to confiscation. In introducing legislation into the English Parliament, the president of the Board of Trade made it abundantly clear that no confiscation was intended, but that the measure was intended to benefit British industries, while providing proper and reasonable means of compensating the owner of the patent if at the end of the war it were found that the German and Austrian governments would provide similar payments for British subjects owning patents in those countries."

Mr. Parker also stated that the Federal Trade Commission was now granting similar privileges under the Enemy Trading Act to American manufacturers and that licenses have already been granted for making articles covered by 60 enemy patents. He regarded these as of utmost promise for American dye producers.

MR. WEBSTER'S ADDRESS.

"The situation in the dyestuff industry is more complicated, perhaps, than in any industry in the world. In the first place, in 1915, the textile industry and other principal consumers of dyes were loaded up with all kinds of dyestuffs. When the war broke out, they had bought high-grade imported dyes under ordinary conditions; they bought dyes that had been intended for other markets, and mixtures compounded ignorantly. These conditions were a prolific source of trouble, and disputes were frequent.

"It was my opinion that probably the greatest service that Mr. McKerrow mentioned would be to bring about a powerful Board of Arbitration to settle these disputes. The courts are less adaptable to changing conditions of business than almost any other branch of the government, and with the profession of law one hundred years or more behind the profession of business it is natural that the effort to deal with the situation as it exists in the dyestuff industry today should be a failure. I know of one single case where substantial injustice was dealt out in the regular channels of a court of justice.

Arbitration Board Should Be Powerful.

"Therefore I believe that there should be a Board of Arbitration in this Association and it should have some power, and the more power that Board of Arbitration has the greater service it can render. A Board of Arbitration should see to it that any question which may be arbitrated before that Board shall be as enforceable as the verdict of a court of law. The Board should have a man with law experience, a man with manufacturing experience and a man with merchandising experience. One man cannot have experience in all these fields, but the man should have as much experience as it is possible to obtain and a broad sense of justice and fairness. The Board in my mind should be composed of three men. A Board of this kind should operate under a special set of rules or statement of principles and rules of procedure that are based on experience with disputes in the industry."

Discuss Tariff Law.

The convention opened Wednesday morning with Mr. Jayne in the chair. The principal address was delivered by Dr. Grinnell Jones, of the U. S. Tariff Commission, who made a strong plea for aid in the collecting of data which would assist the commission in formulating plans for a tariff which would insure a full measure of protection for the American dye industry after the war is over.

DR. JONES ON DYE TARIFF.

"It is not necessary before this audience to discuss the history of the tariff law of September 5, 1916, which raised the duty on dyes and other coal-tar products. I shall merely remind you that the legislation creating the United States Tariff Commission forms a part of this same bill. This law charges the Tariff Commission with the duty of gathering the facts needed for the consideration of questions of tariff policy and requires that all information at its command shall be put at the disposal of the President and Congress, whenever requested. The Commission recognizes that the dyestuff industry presents one of the most important and complex problems which it will have to consider, and is planning to make a report to Congress on this industry.

Commission Seeking Information.

"Last August the Commission sent a questionnaire to many of the leading textile mills asking for a statement in regard to the effect of the dyestuff shortage of 1915 on their business and the extent to which their needs have been met by the growth of the American dyestuff industry. These consumers were also asked to give certain statistical information bearing on the question and to state their opinion in regard to the wisest policy for the country to adopt on the question of the tariff on dyes. Returns have been received from seventy-seven textile manufacturers, and a summarized statement of the replies will be published very soon. The Commission is now seeking information from the manufacturers of dyes, intermediates, and other coal-tar products.

The Underwood Law.

"The Underwood tariff law levied an import duty of 30 per cent ad valorem on dyes, except indigo, alizarin, and dyes derived from anthracene and carbazol, which were on the free list. The act of September 5, 1916, placed an additional duty of 5 cents per pound on the dyes formerly dutiable at 10 per cent ad valorem, and imposed a duty of 30 per cent upon the dyes formerly on the free list. By the same act coal-tar crudes were put on the free list and intermediates were made dutiable at 15 per cent plus 2½ cents per pound. These specified duties of 5 cents in the case of dyes and certain other finished products, and 3 1/3 cents in the case of intermediates, were called special duties.

"The law further provides that these special duties shall remain in force only 5 years, and that they shall thereafter be gradually reduced by one-fifth annually. The law, however, contains another provision, which reads as follows: . . . . 'But if, at the expiration of five years from the date of passage of this Act, the President finds that there is not being manufactured or produced within the United States as much as sixty per centum in value of the domestic consumption of the articles mentioned in Groups II and III (intermediates and finished products) of section five hundred, he shall by proclamation so declare; thereupon the special duties imposed by this section on such articles shall no longer be assessed, levied, or collected.'

"The President of the United States has requested the Tariff Commission to ascertain the facts on which executive action under this clause must be based. It has seemed wise not to wait for the expiration of the five year period before beginning a systematic study of the development and progress of this industry in the United States.

"The schedule which has recently been sent to all manufacturers known to us is designed to ascertain the facts needed for the application of the 60 per cent clause, as well as to secure certain other information which will be helpful to the Commission and Congress in determining the wisest future policy. The Commission is taking a census of the coal-tar products for the year 1917, asking for the quality and value of the production of each intermediate, dye, or other finished product.

"It is, of course, well known in a general way to those familiar with the dye industry that the development of indigo, alizarin, and the vat dyes derived from anthraquinone and carbazol has not kept pace with the development of the azo dyes. Since these branches of the industry are the very important ones which, under the present law, do not get the benefit of the special duty of 5 cents, it is of great importance that the Commission have for the consideration of Congress definite statistical information in regard to the development of the different branches of the industry. For this and other reasons we are asking for detailed information in regard to the production of each separate dye, not simply for grand totals. We hope to publish the totals in as great detail as can be done without revealing the operations of individual concerns. For example, in the cases of aniline and Bismarck Brown there will be so many producers that the total production for the country can be published without revealing the operations of any individual concern.

"It is believed that this information will be of interest and value, not only to Congress, but to the producers themselves. In many other cases the publication of the totals would reveal the operations of individual concerns. In all such cases the dye or intermediate in question will be grouped with others of a similar character, so as to cover effectually the details. In the case of dyes sold under a trade name, whose chemical nature is kept as a trade secret, we are asking that you give us confidentially sufficient information in broad, general terms, such as will enable us to classify properly each such dye. It is especially important that we be able to distinguish clearly between dyes dutiable at 30 per cent. plus 5 cents per pound and those dutiable at 30 per cent. only.

"You will notice that under the present law it is necessary to ascertain both production and consumption of dyes in the United States. It would be impossible to secure complete returns from consumers themselves. It therefore becomes necessary to regard the consumption in the United States as equivalent to the sales of American manufacturers plus imports minus exports. Although the law requires a comparison of the value of the domestic consumption and production, we are asking for the quantity also as a check on the values, and because the quantity is for many purposes a better indication of the growth of the industry than the value.

"One of the difficulties which we foresee is the lack of a generally accepted standard of quality and strength for dyes. If as a result of the deliberations of this Association a generally recognized standard is adopted, the future work of the Commission will be greatly facilitated.

"We appreciate that it will not be easy to bring together the information called for on the schedule, but rely with confidence on the co-operation of the industry toward enabling the Commission and Congress to deal intelligently with an important public question. Although we have sought and secured the helpful co-operation of a number of representative manufacturers, both large and small, in the preparation of this schedule, we realize that it is capable of improvement. We ask you to do the best you can to supply the information in the form called for this year. We shall welcome constructive criticism which will help us to prepare a better schedule for later use. In making suggestions a clear distinction should be drawn between changes which can be made under the present law and changes which would require an amendment to the law.

"The work which the Commission is doing on the special law of September 5, 1916, is not confined to the questionnaire just described. We are also considering very carefully the possibility of improving the law by amendments.

"For example, the new act does not repeal all of the provisions of the old law which are in conflict with the intent of the new law. The list of intermediates mentioned by name is capable of such improvement. Such important intermediates as Michler's ketone and dinitrophenol are not mentioned, whereas the relatively much less important nitrotoluylenediamin and monochlorphthalic acid are included. Very little attention appears to have been paid to intermediates for medicinals or photographic chemicals or flavors. Many suggestions have been made to the Commission in regard to changes in the wording of the law. We have prepared a list of such of these suggestions as seem worthy of serious consideration. We will send a copy of this list to anyone who cares to offer evidence or opinion in regard to the advisability of the proposed changes, and will welcome any additional suggestions.

"The Commission will be glad to arrange for a conference with representatives of the dye industry in the near future. If such a conference appears to be desirable, the Commission will be glad to confer with the officers of this Association, or with any special committee appointed for the purpose of making all necessary plans and arrangements."

TARIFF DISCUSSION.

Leaks in Present Law.

In the discussion which followed, A. Brooking Davis declared that, under the present tariff law, he could not see anything to prevent the German color makers from bringing in certain leuco-dyestuffs as intermediates, and stated that the term "intermediate" should be most specifically defined in the wording of the law in order to make it effective.

"Revision Upward."

"In regard to the question as to the advisability of placing tariff on certain dyestuffs," he continued, "I believe that there are certain groups of dyestuffs and intermediates which are much more difficult to manufacture than others, that it is going to take American manufacturers a longer time to get into the manufacture of, and the tariff should be at least two or three or four times as great on these dyestuffs as on other series."

Referring to the exemption of indigoid dyestuffs, he said: "That statement of indigoid dyestuffs properly includes certain members of four distinct series, which are probably the most important of all the dyestuffs we need. I refer to indanththrene, alizarin proper, the indigo series and the carbazols.

"American manufacturers are not producing these in any quantity. They are going to be most difficult to produce. The production is going to need an investment of many millions, probably greater than all other dyestuffs put together, and it is going to take longer time to work out this group. It would, therefore, appear that a tariff placed on these dyestuffs should be much higher than on all other series, and I think it would be well to include the four distinct series, although they may somewhat overlap each other.

Must Define "Intermediate."

"Why should the law of intermediates be worded so that the tariff is actually retarded for a period of years? If the tariff is removed from intermediates, it permits our competitors to bring intermediates in here and make the dyestuffs in this country and thus avoid paying duty. What is an intermediate? A German concern could manufacture their own dimethylaniline, their own phosgene gas abroad and ship it into this country, convert into dye when it got here by condensing with a simple napthol sulfonic acid and avoid the tariff on Victoria blue.

"We should make a specific definition of an intermediate. How far can a product be advanced in process before it ceases to be an intermediate? What is an intermediate? Is it not extremely important that we limit the number of steps in the process through which a compound can be carried and still call it an intermediate? We must stop at a certain number of steps. If carried beyond those steps it should be called a dyestuff, and placed on the same basis as a dyestuff, otherwise the tariff law will lose its effect, and we will have competition which is almost as great as it was before."

Opposing Interests.

E. S. Alton, of the Edgertyn Aniline Corporation, New York, declared that one of the biggest questions confronting the organization was the consumers of color before the war who used all their influence and brought all their influence to bear in Congress to prevent a tariff being placed on dyestuffs and intermediates. "And I think," he said, "that the American Cotton Association used every interest possible to prevent a tariff being put on dyestuffs before the war. Whether these interests are willing to co-operate with manufacturers of dyestuffs in placing a tariff on dyestuffs is a question which should be discussed between this association and the American Cotton Manufacturers' Association and the Woolen Manufacturers' Association. We should appoint a committee and get aid in placing the tariff high enough. They represent a power which we have got to get working with us before we can get the tariff placed on dyestuffs and intermediate products."

Opposition Dwindling, Says Dr. Herty.

Dr. Charles H. Herty, editor of the Journal of Industrial and Engineering Chemistry, said: "I had a conversation a few days ago in North Carolina that interested me very much as showing the change of opinion among a certain crowd. They had not been very much in sympathy with our efforts. We all must remember that one reason why we got this tariff bill was the hearty co-operation of nearly all of the consumers with the producers of dyestuffs. We have good reason to feel that the consumers of textiles have come across very squarely since this movement started. But there was a certain crowd in the country, typified by certain manufacturers in North Carolina, who were largely responsible for certain exceptions in the bill. Talking with a large mill owner, he brought up the subject of the dyestuff industry to me and remarked that 'I understand that we are going to give the dye people a fairer showing than they have had in the past. We mill men realize that we must depend on the American manufacturer and since we have had a revelation of the German methods, in peace and war, I have made up my mind that I do not want any more German dyes. We are going to see that the American manufacturers are our right-hand aids in all our work.'

"I think the American chemists should get out their pencils and find some way to shoot holes into the present tariff law, about bringing in finished dyestuffs in the form of intermediates, and take it up with the Tariff Commission."

Have Variation in Our Favor.

This evoked an enthusiastic outburst of approval as the assembled manufacturers grasped the full significance of the mill owner's change of view.

Continuing his remarks, Dr. Herty took up the question of wiping out the incongruities in our tariff laws and putting intermediates on the same basis with dyestuffs. "The object is," he said, "to build up the American dyestuff industry. The essential thing is the building up of the domestic manufacture of intermediates. It is more difficult to make certain intermediates than it is to make certain finished dyes. The law, as it stands now, gives a higher tariff on an easier made product than it gives on a more difficultly made product. Suppose the thing were shifted around the other way. That would undoubtedly result in a higher tariff on easier made products than on intermediates. The variations are against us. Why not have the variations in our favor, and then we can get at the root of all these complicated questions?"

30% Duty Too Low, Thinks Mr. Alton.

That the Germans would still be able to sell dyes here at a profit in spite of the present tariff law, was the opinion of Mr. Alton, who held that "German labor is so cheap and German raw materials procured so cheaply that they will try to come back into the countries in which they have formerly had their biggest returns.

"A duty of 30% seems small to them," he continued; "50% is also small, because they sold at such low prices, and American manufacturers will not be able to compete even with 50% duty. Vat colors is one of the greatest industries in Germany. We have no vat colors to offer except in small quantities, so they are still as strong on these colors as ever. If they do nothing else but send in vat colors, the big cotton manufacturers will drop back to them because that is the only fast cotton dye. If you reduce the tariff we will not advance any longer in vat colors. We will remain manufacturing what we are making today and cease to go any further."

More discussion followed, resulting in the decision to appoint a committee to make specific recommendations to the Tariff Commission through Dr. Jones.

Organization Committee Holds Power.

Dr. Matthews then returned to the platform to present the report of the organization committee, which asked that the committee be continued in power until the first annual meeting of the association, to be held, it was suggested, on Wednesday, March 6, in the same building. The resolution, which was passed unanimously follows:

Resolved: that the Organization Committee appointed by the chairman be empowered to continue to act as such until the first annual meeting of the association with power to

1—Prepare and file a certificate of incorporation;

2—Prepare by-laws for submission at the annual meeting;

3—Arrange the time and place of the annual meeting;

4—Entertain and pass upon applications for membership;

5—Confer with the Tariff Commission and report at the annual meeting.

And be it further resolved: that the temporary chairman, secretary and treasurer elected by this convention continue to act as such until the annual meeting.

The organization committee further suggests as a matter to be considered by the convention, the name of "Dyestuffs Association of America" as the name of this association.

The convention then adjourned to meet again March 6, at 10:30 o'clock.

FIRMS AND REPRESENTATIVES.

A Partial "Who's Who" of the Convention.

The Chemical Engineer regrets greatly that there was no official attempt made to take a complete record of those who attended the first meeting of the dyestuff industry in this country. The following list, which, however, is not complete (though not through any fault of its compiler) was prepared for Mr. McKerrow by Treasurer Charles Jenkinson:

The Sherwin-Williams Co., New York; *J. O. Hasson, manager; W. S. Woodrow, eastern manager.*

The Meth-O-Lene Co., Inc., 81 Fulton street, New York; (Tatamu, Pa.) *Frank S. Bache.*

The L. B. Fortner Co., 36 Strawberry street, Philadelphia, Pa.; *Louis B. Fortner.*

Dana & Co., Inc., 111 Broadway, New York; *E. C. Hull.*

Bowring & Co., 17 Battery place, New York: *Frank E. Morgan, chemical department.*

Dye Products & Chemical Co., Inc., 200 Fifth avenue, New York; *Clarence K. Simon, president; Morris Simon.*

John D. Lewis, Providence, R. I., *Mr. Stephen.*

Calco Chemical Co., 141 Milk street, Boston, Mass.: *J. H. Crockroft, Boston representative; F. Miller Fargo, Jr., sales manager, Woolworth building,* New York.

New York Commercial Co., 20 Vesey street, New York; *E. G. Erikson.*

The Barrett Co., 17 Battery place, New York; *Herbert G. Sidebottom, technical service manager; D. W. Jayne, manager chemical department.*

Dicks, David Co., Inc., 302 Broadway, New York; *Frank Hartley (146 Summer street, Boston, Mass.) and Albert David.*

U. S. Conditioning & Testing Co., 340 Hudson street, New York; *Edw. W. Pierce.*

E. Puigdengolas, S. C., 299 Broadway, New York: *Luis Guillo, representative. Also Barcelona, Spain.*

Chas. A. Johnson & Co., 55 Franklin street, New York; *James F. Hurley*

Geo. H. Morrill Co., Norwood, Mass.; *O. L. Peabody; Olney P. Anthony, chief chemical staff.*

INORGANIC CHEMICAL SYNONYMS

A Novel Work of Reference for Student and Chemist

By Elton R. Darling[*]

Although Intended Primarily for the Student, It Is Believed That the Following Compilation of the Various Terms Employed to Designate Inorganic Chemicals Used in the Industries, Will Prove a Convenience to the Experienced Chemist. The Writer Claims No Originality for the Synonyms, but Only the Bibliographical Research of the Material at Hand. Part II Will Appear in the Next Issue.

PART I.

This article is the result of the writer's experiences in the laboratory and his dealings with young chemists from the universities. It has been prepared in the hope that it will fill a need which has repeatedly manifested itself in the struggles of students to grasp quickly the laboratory significance of many chemical terms often met with in the persual of the average popular "trade" treatise describing this or that process of industrial chemistry.

"Chemical Colloquialisms."

It is a matter of common knowledge that some of the chemicals used in commercial work are known by as many as twenty varying terms or synonyms. It is also true that a single chemical may be known by terms which differ slightly or greatly according to the geographical location in which it chances to be in use. In short, colloquialisms spring up in the language of chemistry quite as readily as they do in any language, and such variations in nomenclature are often confusing to student and chemist alike. This is particularly true when the unhappy individual suddenly finds himself obliged to "read up"—in a hurry, perhaps—on some subject with which he is not thoroughly familiar.

Even in technical works devoted to the chemical industries, two writers will frequently employ different terms to designate the same chemical compound. The result is sometimes guesswork and ultimate abandonment of the treatise for another; at the very least it means annoying delay, accompanied by the fervent wish that one had a ready means of ascertaining whether "Alum Flour," "Potash Alum," and "Octahedral Alum Salt" all mean our laboratory friend Aluminum Potassium Sulfate, or three entirely different compounds of aluminum.

The writer himself has frequently felt this need and knows it to exist. It is, indeed, surprising what a large percentage of students are familiar only with the true chemical terms and quite in the dark as to their synonyms. It would seem fitting that the latter part of the courses in inorganic chemistry should devote some time to this subject. In the absence of this, the following list of some of the more common chemicals and their synonyms has been prepared. The writer claims no originality for the synonyms, but only the bibliographical research of the material at hand.

While this work is intended primarily for the student, it is believed that the practical chemist will profit by it.

Fundamentals.

For the reason that no work of reference would be quite complete without the inclusion of such fundamental matter as tables of the elements, atomic weights, specific gravity, etc., together with comparisons of the various systems of weight, capacity, volume and temperature measurement, the preface to the present compilation will be further expanded by the presence of these facts and figures.

THE ELEMENTS.

All of the elements at ordinary temperature are not in the solid state. Two are liquids and ten are gases. The liquid elements are bromine and mercury. The gaseous elements are oxygen, hydrogen, chlorine, fluorine, nitrogen, argon, helium, krypton, neon, and xenon.

The solid or metallic elements have at varying temperatures been liquified with the exception of carbon. This element can only be softened when subjected to the highest known temperature.

The table of atomic weights was compiled by the International Committee on Atomic Weights consisting of F. W. Clarke, W. Ostwald, T. E. Thorpe, and G. Urbain.

Their Symbols and Atomic Weights.

Aluminum	Al	27.1
Antimony	Sb	120.2
Argon	A	39.88
Arsenic	As	74.96
Barium	Ba	137.37
Bismuth	Bi	208.0
Boron	B	11.0
Bromine	Br	79.92
Cadmium	Cd	112.40
Caesium	Cs	132.81
Calcium	Ca	40.07
Carbon	C	12.00
Cerium	Ce	140.25
Chlorine	Cl	35.46
Chromium	Cr	52.
Cobalt	Co	58.97
Columbium	Cb	93.5
Copper	Cu	63.57
Dysprosium	Dy	162.5
Erbium	Er	167.7

Zinc	Zn	65.37
Zirconium	Zr	90.6

Their Discoverers and Dates of Discovery.

In the following list Helium will be found twice; the first date, 1868, refers to its discovery in the sun by Lockyer. It was again discovered in 1895 by Ramsay, who found it among the elements of the earth.

Although Uranium was discovered in the early part of 1780 its radio-active properties were not known until 1896.

	Mercury	This was known to the ancients
	Gold	This was known to the ancients
	Silver	This was known to the ancients

Occurrence of the Metals in Nature.

Aluminum as the silicate.
Antimony as the sulfide.
Arsenic as the sulfide.
Barium as the sulfate.
Bismuth as the oxide, sulfide. Also metallic.
Cadmium as the oxide, carbonate, and sulfide.
Calcium as the carbonate, sulfate and silicate.
Chromium as the oxide.
Cobalt as the sulfide.
Copper as the sulfide, oxide and carbonate.
Iron as the oxide, sulfide and carbonate.
Lead as the sulfide.
Magnesium as the carbonate, sulfate, and silicate.
Manganese as the oxide.
Mercury as the metal or sulfide.
Nickel as the sulfide.
Silver as the metal or sulfide.
Sodium as the chloride and silicate.
Strontium as the carbonate, sulfate, and silicate.
Tin as the oxide.
Zinc as the oxide, carbonate, and sulfide.

STANDARDS OF WEIGHTS AND MEASURES.

By a mutual action taken by the governments of the world the International Bureau of Weights and Measures was established near Paris on the 20th of May, 1875. The standards were made of platinum-iridium in a ratio of nine parts of the former to one part of the latter. The originals are kept in the archives of the Bureau of Standards in Paris.

Duplicate standards have been sent to the various governments who are members of the bureau.

The standard of length is the meter and is a duplicate of the International Standard Meter. It was originally defined as the forty-millionth part of the quadrant of the meridan at Paris, and is the distance between two points at 0° C. on the original standard platinum-iridium bar.

The kilogram is the weight of a cylinder of the same alloy at 0° C. made in vacuo.

The litre is equal to a cubic decimeter. This is determined by measuring this quantity of distilled water at 4° C., which is the temperature of its greatest density. All weighings are made in vacuo.

As the metric system is the standard used by the chemist, such tables will be given. But for the student, comparisons with the other systems will be given, as the metric system is not being universally taught as yet.

CHEMICAL SYNONYMS.

Aluminum 27.5.

Specific gravity 2.7, fuses at 450°C.; melting point 657°C.; has a boiling point above 2200°C. It is trivalent but is also looked upon (when expressed as the double atoms) as a single sexivalent atom.

The name aluminum is derived from the Latin word alumen. Alumen was a term used by the Romans in reference to bodies possessing an astringent taste.

The first mention made to alum was that of Pott, who in 1746 stated that the basis of it was clayey material. In 1754 Marggraf confirmed Pott's views, but added that there was a difference between alumina and lime.

Davy in 1807 and Oersted in 1824 tried to purify the metal, but were unsuccessful. In 1827 Wohler repeated the work of Oersted, and not having success, turned to the decomposition of the chloride with potassium and thus was the first to obtain the metal in its pure state.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By Carleton Ellis and A. A. Wells.*

PART X

CHLORINATION OF PARAFFIN HYDROCARBONS.

In the production of chlorinated compounds of saturated hydrocarbons, *Blanc,* (U. S. patent 1,248,065, Nov. 27, 1917) makes use of light rays for activating the reaction. In addition to the activating effect of the light, catalyzers may also be used. An apparatus for carrying out the process is described, see Fig. 1, in which a chamber containing the hydrocarbon to be chlorinated is fitted with windows, transparent to the light waves which are employed. In the illustration, the right hand tube is for the admission of chlorine, the separatory funnel is for the addition of hydrocarbon; next to the separatory funnel is a reflux condenser and at the left is a tube for the return of material which has passed through the apparatus and is not sufficiently chlorinated. Ultra violet light may be used, the position of the lamps being indicated by the two electrical bulbs located on the sides of the chamber. The outlet tube at the lower left-hand corner is for drawing off the chlorinated material.

A method for absorbing the hydrochloric acid given off by the reaction, thus purifying the chlorine which is unabsorbed and making it suitable for return to the chamber, is described; also means for fractionating the chlorinated material and returning those portions which are not sufficiently chlorinated. It is stated by Blanc that small amounts of moisture are favorable to chlorination and for this reason the chlorine is bubbled through water before entering the reaction chamber.

CHLORINATION OF AROMATIC HYDROCARBONS.

A process for the manufacture of side chain derivatives of chlorine from toluol is proposed by *Gibbs* and *Geiger* (U. S. patent 1,246,739, Nov. 13, 1917). They note that among the various methods for the chlorination of toluol in the side chain are the following:

(1) By passing chlorine into boiling toluol in the presence of light until a certain weight of the chlorine is absorbed, a mixture of the different chlorine compounds is produced. The principal products are those in which the chlorine is substituted in the side chain, but there are also present compounds containing chlorine in the ring.

(2) On mixing gaseous toluol in excess and chlorine gas in the presence of light and a catalyst, only a portion of the toluol is attacked with the production of benzyl chloride. The latter is mixed with unattacked toluol and the catalyst and must be subjected to a purification process which adds to the expense of the process.

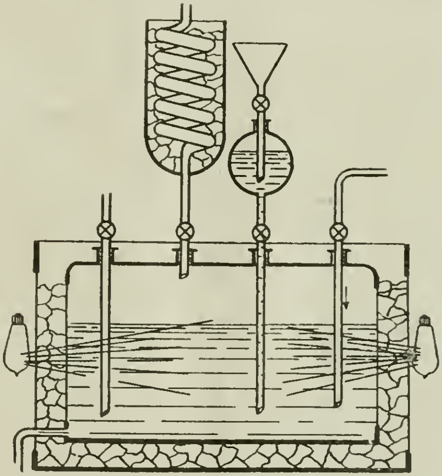

Figure 1.—Blanc's Apparatus for the Chlorination of Aliphatic Hydrocarbons.

(3) By mixing gaseous toluol with an excess of chlorine gas in the presence of a catalyst a mixture of benzyl chloride, benzal chloride, benzotrichloride, chlor-toluol, chlor-benzyl chloride, etc., is produced. The action is somewhat analogous to (1,) above mentioned, due to the fact that the reaction takes place in successive stages and yield of any one desired product cannot be exactly controlled.

Gibbs and Geiger state that when toluol in the vapor form is mixed with chlorine gas in the definite theoretical proportions to produce chlorinated side chain products and the mixture exposed to ultra violet rays, the bodies desired are produced in greatly increased yields and without the production of interfering by-products. The operation is rendered continuous by constantly feeding to the zone of light the vapors of toluol and chlorine gas and by carefully regulating the speed at which these reacting substances enter the reaction chamber a high degree of purity results. They state it is advisable to work without the presence of a catalyst, as it is not essential to the reaction and would tend to contaminate the product.

---

*All rights of publication in book form reserved by the authors. Consulting Chemists and Chemical Engineers, 92-98 Greenwood Ave., Montclair, N. J.

According to this process benzyl chloride, benzal chloride and benzotrichloride may be produced according to the proportion of chlorine employed.

Examples are the following:

The reaction chamber, consisting of material resistant to all substances taking part in or produced by the reaction, is swept clear of air by the introduction of an inert gas, such as carbon dioxide. This reaction chamber is provided with a lamp such as the quartz mercury lamp. The liquid toluol is then fed by means of a pump at the rate of 60 grams per minute into a vaporizer heated by a resistance coil which converts the toluol into the gaseous condition. The vapor is then fed from the vaporizer into the reaction chamber. The chlorine is delivered from the cylinder or electrolytic cell through a measuring apparatus directly into the reaction chamber through a tube concentric with that of the toluol tube at the rate of 46 grams per minute. The product of the reaction collects on the bottom of the chamber and is drawn off at intervals without the introduction of air. The hydrochloric acid formed is led off through the top of the chamber and absorbed in water.

For making benzal chloride or benzotrichloride the features outlined above are the same except that the rates of delivery of toluol and chlorine are different. To produce benzal chloride the toluol is delivered at a rate of 60 grams per minute and the chlorine at 92.5 grams per minute. For benzotrichloride the rates are, toluol 60 grams per minute, chlorine 139 grams per minute.

Gibbs and Geiger are employees of the Department of Agriculture and have dedicated their patent rights to the public.

PEPPERMINT OIL.

It is a well known fact that good quality peppermint oil when used as a flavoring for certain candies or sugar preparations, such as ordinary mint tablets, loses its fine flavor on long standing. In the writer's laboratory a number of samples of mint tablets were exposed to the action of ultra violet light in order to test the stability of certain mint oils in the manufacture of confections. It was found that a few hours' exposure to the light afforded approximately the same ageing effect as standing on the shelves for a period of several months. The procedure appears to be a ready method of testing materials of this class to quickly determine their keeping qualities.

VARIOUS OILS AND RESINS.

In the writer's laboratory numerous experiments have been made to test the effect of ultra violet light on various oils, resins, etc., especially in regard to the bleaching action and polymerization. A résumé of some of these tests follows. The lamp used was a Cooper-Hewitt quartz burner, using one hundred and fifty volts at three and a half amperes.

The following oils, among others, were subjected to the action of ultra violet rays to ascertain whether any bleaching effect was exerted: Crude cottonseed oil, linseed oil, crude whale oil (No. 3) and lubricating oil of medium body and strongly fluorescent. The oils were exposed in shallow pans in layers about three-sixteenths of an inch thick and spaced about eleven inches from the burner. After three hours' exposure the linseed oil had a very heavy film over the surface. The cottonseed and whale oils had slight films, while the surface of the lubricating oil was apparently unaltered. After six hours' exposure the cottonseed oil had greatly increased in viscosity, the linseed and whale oil had commenced to gelatinize and the lubricating oil had become slightly darker. At the end of thirteen and a half hours the cottonseed oil had gelatinized and was slightly bleached. The linseed oil had become a stiff jelly and the linseed odor was diminished. The color was apparently unchanged. The whale oil was considerably deodorized and slightly bleached. The lubricating oil had become somewhat darker, but the fluorescence had completely disappeared. (See Ellis, U. S. patent 1,089,359, Mar. 3, 1914.)

On exposure of whale oil in layers about three-sixteenths of an inch in thickness and placed four inches from the burner for ten hours, a dark amber-colored jelly resulted, the odor of which was very faint as compared with the original oil. Crude cottonseed oil exposed for seven hours at a distance of six inches from the burner gave a stiff amber-colored jelly. The jelly was considerably lighter than the original oil and the iodine value had fallen to 56. China wood oil treated under the same conditions gave a hard jelly which on exposure for an hour or so became so brittle that it could be easily pulverized. The powdered product was almost white. The iodine value of this product was 93. Linseed oil treated in the same manner gave a resilient translucent jelly of practically the same color as the original oil. A highly refined cottonseed oil placed four inches from the burner for thirteen hours gave an amber colored jelly of practically the same color and consistency as the crude cotton oil. Castor oil when exposed at a distance of three inches from the burner for ten and a half hours gave a product which was identical in appearance and odor to that obtained from cottonseed oil. Red oil (crude oleic acid) when exposed for fourteen hours at a distance of four inches from the burner gave an entirely different product from the other oils. It was noted that fumes were given off at a very low temperature. At 85° C. slight fuming was noticed. At 110° C. copious fumes were given off. The manner in which this oil thickens suggests crystallization, while in the case of cotton oil or castor oil the solidification resembles coagulation. In the case of red oil a thin film forms over the surface and apparently protects the under layer from further action until this film is removed. The oil when completely solidified is hard without any suggestion of tackiness. It is perfectly black and practically odorless. A highly refined edible corn oil when placed four inches from the burner for fourteen hours gave a jelly of a very light yellow color. The change of a fatty oil from a liquid to a solid state is very gradual, the oil becoming slightly viscous at first, then increasing gradually in viscosity until it finally assumes the jelly form. Immediately before the mass commences to solidify a large number of small bubbles usually appear beneath the surface of the oil and these may still be observed after the oil has become completely solid.

Comparative Rapidity of Polymerization.

It is of interest that, although the gelatinized crude cottonseed oil was considerably lighter than the original crude product, the gelatinized refined oil as prepared above was much darker than the original refined oil. The average temperature of the oil during these experiments was 110°. It was noted that crude cottonseed oil, at relatively low temperatures, fumed slightly under the action of ultra violet light, while the refined oil did not give off any fumes until the temperature had reached about 160° C. Even at that point the fuming was only slight. The conclusion which may be drawn from these experiments and from some others carried out under practically the same conditions is that crude oil polymerizes and gelatinizes more rapidly than refined oil.

The question arose as to whether this gelatinizing effect was due to oxidation or mainly to the action of the rays themselves. In order to determine this, oil was placed in a tubular quartz container and the opening carefully sealed. The tube was then exposed to the action of the ultra violet light for five hours at a distance of four inches from the burner. At the end of this time the oil had become thickened so that it would no longer flow in the tube. The experiment was then repeated. This time the tube was filled completely with oil at the temperature at which the oil was to be exposed to the ultra violet light and the open end was carefully sealed. The tube was exposed to the ultra violet light for ten hours and at the end of this period the bubbles previously mentioned had begun to appear and the oil had become highly viscous. Thus, ultra violet light in the absence of oxygen is able to thicken and polymerize some fatty oils. In the presence of oxygen, however, the results of a number of tests indicate the solidification of unsaturated fatty oils under the influence of the ultra violet light is due jointly to oxidation and polymerization.

In one case ordinary cottonseed oil was mixed with five per cent. of sulphur and exposed to the action of ultra violet light for three hours at 150° C. and remained liquid after the treatment, but an oil which had been exposed until it was practically at the gelatinization point and then had the same amount of sulphur added, on exposure to ultra violet light in the same way yielded a black rubber-like solid.

In view of the results obtained with unsaturated fatty oils, a sample of oil which had been hydrogenated to a titre of 54° C., was exposed to the ultra violet light. This oil was exposed in the same manner as the other oils, but for a period of thirty hours. At the end of this time practically no change was noted either in color, odor or viscosity. The stability of the oil under these drastic conditions was of interest.

In another case a mixture of equal parts of rosin and corn oil having the consistency of honey was exposed in a thin layer to the action of ultra violet light at a distance of four inches from the burner. After five hours the product had become extremely viscous and was somewhat darkened. A longer exposure of another sample at a distance of fourteen inches from the burner gave a product of about the same consistency, although much lighter in color. The carbonizing or discoloring effect of exposure very close to the burner was repeatedly noted. The discoloration may be due partly to the rays and partly to local superheating of the upper layers of oil.

In order to obtain an idea of how long an exposure is necessary to completely solidify the oil when exposed to the ultra violet light in a very thin film, a layer of cotton oil about one-sixteenth of an inch in thickness was exposed at a distance of four inches from the burner and the consistency noted every minute. The oil commenced to thicken almost immediately and at the end of fourteen minutes had completely solidified to a very thick jelly. To determine whether thicker layers of oil were opaque to the ultra violet rays, cottonseed oil was exposed at a distance of four inches from the burner, the depth of oil in this instance being one and one-half inches. After an exposure of seven and one-half hours it was found that the entire mass of oil had become solid and was nearly uniform throughout, the product being a dark colored jelly.

An interesting fact about some of the gelatinized products mentioned above is that on exposure to the air for about twenty-four hours they become opaque and quite brittle. If the product is tacky on removal from the burner, the surface loses its tackiness in a very short time. This drying progresses through the film until finally there forms a brittle mass which can be easily powdered.

Oxidation of Soya Bean Oil.

Experiments on the oxidation and polymerization of soya bean oil have been carried out by *Taverne* (Z. angew. Chem. 27, 1, 249-51, 1915). Oxidation in the air at room temperature was effected by Fahrion's method. The hydroxy acids of three grams of oil on ten grams of cotton yarn were determined after thirty days' exposure and found to be 38.4%. Oxidation at 70° was carried out in the apparatus of Genthe, and was complete in thirty hours. Oxidation in air at 150° was also carried out, according to Genthe, by heating in a beaker. The molecular weight rose in ten days from 710 to 1730, a fact which indicated polymerization or condensation along with the oxidation. The oil became solid and contained 31.8% hydroxy acids and 63% fatty acids soluble in petroleum ether, while the iodine number decreased to 64.8. Genthe states that siccatives are inactive in ultra violet rays, but Taverne, on the contrary, obtained complete oxidation in 45 hours. A lead manganese rosin compound containing 6.28% lead and 5.76% manganese was found to be the most active agent for hastening oxidation. On exposure to ultra violet light at 70° oxidation was complete with 5% siccative in 580 minutes.

Olive Oil.

Lesure (J. Pharm. chim., 7, 1,575-6) has observed that exposure of olive oil for an hour to ultra violet light caused an increase of more than 5% in the acidity.

Making Fatty Acids from Petroleum.

A process of deblooming hydrocarbons and converting them into fatty acids and esters is described by *Gray*, (U. S. patent 1,158,205, Oct. 26, 1915). The apparatus recommended (see Fig. 2) consists of a horizontal cylindrical still in which the hydrocarbon oil to be treated is placed. From the inner top portion of this still is suspended a row of lamps emitting ultra violet rays. The burners are in close contact with the surface of the oil, usually from two to six inches above the oil. A perforated coil is located on the bottom of the still for the admission of air, oxygen or ozone. Slightly above this perforated coil is a screen which carries catalytic material such as metals, their bases or salts, supported on porous granular material. The still may be heavily constructed to work under pressures up to five atmospheres.

In the deblooming operation, the oil (lubricating oil. paraffin wax, etc.,) is heated to from 50 to 120° C. by means of a high pressure steam coil. The oxygen-carrying gas is then forced through the oil, agitating the latter and in so doing exposing continuously new portions of the oil to the action of the ultra violet light. In the production of esters or fatty acids the temperature is maintained at from 90° to 175° C. and the process carried on as for deblooming. Samples of oil may be drawn from time to time to determine the progress of the reaction. The length of time required for the treatment will depend upon the hydrocarbons being treated, as these vary in their susceptibilty to oxygenation or esterification. Gray states that he has been able to convert 75% of a given quantity of hydrocarbons into fatty acids by this process. The catalyzers which he especially recommends for use in this process are caustic soda or caustic potash. In one instance a 220-volt mercury vapor lamp was placed four inches from the surface of the oil which was gently agitated with air. In this case it required approximately eight hours to debloom a depth of three inches of oil covering a surface of one square foot per lamp. In treating oils for deblooming it is stated to be essential that the temperature be kept below 100° C., otherwise discoloration of the oil will be brought about, making it unsuitable for use without further purification. The temperature is usually maintained by the heat derived from the lamps and in some cases it is even necessary to pass cooling water through the coil in the still.

Cracking Mineral Oils.

The Continental Caoutchouc and Gutta Percha Co. (French patent 469,948, March 21, 1914) produce lighter oils from high boiling fractions of mineral oil by the following method: The fraction of high boiling point is heated with a catalyst such as aluminum chloride, with or without mercuric, ferric, vanadium, or other chloride, or with aluminum in a stream of dry hydrochloric acid gas. It may be exposed in the form of spray to ultra violet rays or to the silent electric discharge in presence of a catalyst. The process is continuous. Gaseous products may be obtained by heating to a higher temperature in closed vessels.

Linseed Oil—Uviol Oils.

Genthe (German patent 223,419, Aug. 24, 1907; Scientific American, 1908, 255) offers a process of bleaching linseed oil, etc., by the action of short wave light and oxygen. The process is carried out by mixing the material intimately with air and allowing short wave light to impinge on the mixture. A mercury vapor lamp which produces ultra violet rays in abundance is made of a special glass which transmits waves as short as 253 millionths of a millimeter. Twenty ultra violet lamps are immersed in a tank containing one ton of crude linseed oil, heated to 176° F., into which air is simultaneously introduced in fine bubbles. Under the influence of the ultra violet rays the oil absorbs one twentieth of its weight of oxygen and becomes colorless, brilliant and limpid. The air is forced through the oil by a pressure equivalent to 10 feet of water. A stirring device provided with hollow arms through which the air may be blown is also used, to agitate the oil. It is stated that 1,000 kilos. of linseed oil can be bleached with an expenditure of 60 kilowatt hours for current, and 1,500 cubic meters of compressed air, under a pressure of 0.3 atmospheres, the total cost being stated to be about two dollars. Genthe (Chemical Technology and Analysis of Oils, Fats and Waxes, Lewkowitsch, Vol. 11, 1914, 33) also bleaches linseed oils with the Cooper-Hewitt mercury lamp for purposes of varnish manufacture; he also prepares "boiled oil" by exposing raw linseed oil to the ultra violet light of an "uviol" lamp. Recently, vegetable oils, stated to have been bleached by exposure to ultra violet rays, have been placed on the market under the name of "Uviol oils;" no published information as to these oils is available however.

Action of Ultra Violet Light on Varnishes.

In the writers' laboratory a large number of samples of varnishes of various grades have been exposed to the action of ultra violet light to determine its bleaching activity. The behavior of varnishes when subjected to the light varies greatly, depending on their composition. Some samples were considerably bleached, while others were darkened, others showed no effect. Some samples formed a heavy skin over the top. One sample especially, became almost solid after an exposure of eight to ten hours in one-half inch layers. In some cases the varnish was floated on a layer of water to prevent overheating. In other cases the samples were enclosed with the lamp in a chamber and inert gases or steam passed through the chamber during the light treatment. There did not appear to be any great difference in results when taking these precautions as compared with samples exposed to the atmosphere. Samples of linseed oil were also exposed under the same conditions. In most cases the oil was considerably bleached and with raw oil, practically no skin was formed over the top. With boiled oil, a film was formed on exposing linseed oil to the action of the light for six hours, when free access of air was allowed. In one case where the oil was exposed in a thin layer over water, the oil became turbid and apparently a very stable emulsion was formed. In another case a sample of raw oil was exposed for seven hours in a closed chamber in an atmosphere of steam. The oil, which was quite dark at the beginning, was bleached to a light straw color.

Asphalt.

In the action of light upon asphalt, which makes the latter more insoluble, *Gödrich* (Monatsh. 1915, *36*, 535) asserts that oxygen plays the role of a catalyzer. By the action of sulphur chloride upon asphalt the light insensibility is increased, but this is not proportional to the per cent. of sulphur in the different varieties. Solutions of asphalt show absorption bands in the blue and the yellow, but in the asphalts containing sulphur the latter are lacking. Asphalt is sensitive towards monochromatic light for the entire range of the spectrum and into the ultra violet.

Cumaron Resin.

Cumaron resin, produced by treating solvent naphtha with sulphuric acid, on exposure to ultra violet light for a period of three hours at a distance of a few inches from the light, was sensibly darkened. (J. Ind. Eng. Chem. 1916, 800.)

Synthetic Resins.

Mathews and *Elder* (British patent 11,635, 1914, J.S.C.I., 1916, 192) claim that compounds of sulphur dioxide and unsaturated hydrocarbons (pseudobutylene, propylene, amylene, and ethylene) are polymerized on exposure to ultra violet light or by heating. The butylene body gives a transparent film and renders celluloid less inflammable. A review of synthetic resins is given by Elder, (Kunstoffe, 1916, 6, 45) with special reference to the patent literature.

Polymerized Acrylic Acid Ester.

A substitute for drying oils as a medium for paints, varnishes, and impregnating agents for fabrics, wood, etc., proposed by *Rohm* (J.S.C.I., 1917, 296, German patent 295,340, June 5, 1915) consists of a solution of polymerized acrylic acid ester, in acetone, lower fatty esters or other solvents. The acrylic esters may be prepared from allyl alcohol, glycerine, lactic acid, etc. When exposed to sunlight or ultra violet light, they are transformed into a colorless, transparent, very elastic (not gelatinous) tough mass, which is soluble in solvents for oils. Alternatively the ester may be mixed with a solvent, and the mixture polymerized. The polymerized ester dries rapidly, resists many chemical agents and is not readily affected by exposure to weather.

Fabric-Staining Oils.

In order to ascertain the liability of oils to stain textile fabrics *Gray* (Oil, Paint & Drug Reporter, Aug. 9, 1915) proposes to expose pieces of tape, treated with the oils, to the light from a Cooper Hewitt quartz lamp, using a standard oil for purposes of comparison. A half hour exposure at a distance of six inches from the lamp, was found to be sufficient to develop a stain with oils likely to discolor fabrics.

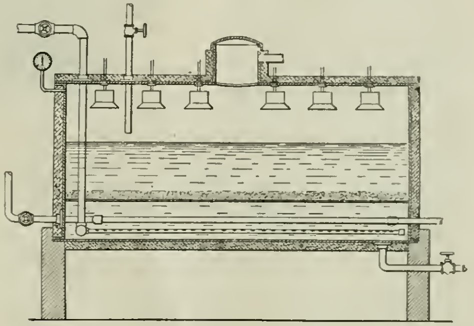

Figure 2.—Gray's Apparatus for Conversion of Hydrocarbons Into Fatty Acids.

Hydrogenation of Oleic Acid.

The effect of the rays from an iron arc on the hydrogenation of oleic acid is described by *Curtis* (Journal of Franklin Institute, 1917, 880). The oleic acid was placed in a quartz flask which was fitted with a long air condenser and hydrogen gas was passed in. The arc was placed 1.5 centimeters from the flask and the exposure continued for six hours, when the degree of hydrogenation was determined by the iodine numbers. It was concluded that there was no acceleration in hydrogenation of oleic acid due to the action of the light. Experiments performed without illumination showed that the amount of saturation was practically equivalent in each case.

Oven dried lacquered leather, before further drying, is exposed by Heyl (Chem. Abs. 1917, 2417; Holland patent 1,970, May 15, 1917) to the action of artificial light rich in ultra violet rays and to ammonia vapors.

Patent Leather.

Lumbard, (J. Am. Leather Chem. Assn., 84, 1915) discusses the use of ultra violet in the manufacture of patent leather. It is claimed that the exposure of the varnished surfaces to the action of mercury vapor lamps gives the same result in one and one-half hours as is obtained by several days' exposure to sunlight. Lumbard claims that better results are obtained if the extreme ultra violet rays are filtered out.

(To be continued in the February issue.)

CHEMICAL INVESTIGATION
EFFICIENCY & CONTROL

CONDUCTED BY CHARLES B. DAVIS, F.C.S.

ALL classes of work covered by the following subjects will be done for readers of "The Chemical Engineer" through this department by Mr. Davis: Special research of every description; analysis and reproduction of any commercial product; prevention of waste and utilization of by-products on the most economical basis; valuation of raw materials; food analysis, and disputed points in regard to adulteration, labeling, and the enforcement of pure food laws; bacteriological and enzymatic examinations, including fermentation tests, pure yeast cultures, beverages of all kinds; development of chemical inventions and industrial processes; examinations and advice on special machinery.

Inquiries of a minor character will be answered on this page, while major matters involving personal investigations, analyses, etc., will, if desired, be treated confidentially through the mails. All questions, materials for analysis, or letters leading to the opening of negotiations for special work will receive prompt attention if addressed to

CHARLES B. DAVIS,
Care of "The Chemical Engineer," 118 East 28th Street,
New York City.

O. A. S.—Sandarac, which gives the characteristic odor you find in testing, is due to that type known as Callitris quadrivalvis. Callitris verrucosa contains Pinene and therefore will not evolve the same odor.

A. B. T.—The ochre sample received from your miner has been submitted to careful chemical analysis, but I am sorry to report that it cannot be used for the purpose you mention. Its chief use will be found in the window shade and low grade paper lines.

A. A. F.—Your trouble is due to too high a content of sulphur while vulcanizing. This always cause the cracking you mention. The sample you sent me contained such a high percentage as to make it extremely brittle. I would strongly recommend you to reduce this constituent at once or your product will be in no way merchantable.

M. S. D.—The reason your mashes are not fermenting dry enough is because your enzymic conversion has been impaired by too high a content of acid. You had better add a little active diastase directly to the mash after first reducing the acidity to at least 0.12%.

Send me samples of each batch for investigation as to the transformation of the starchy matter and acidification.

H. R. T.—The formulae of the minerals you mention in your last letter are given below. Regarding those you are about to forward me for complete analysis, would state that absolute representative samples should be taken, by the usual method of quartering, etc., and one pound quantities sent me.

Microcline	$KAlSi_3O_8$
Sillimanite	Al_2SiO_5
Zircon	$ZrSiO_4$
Rutile	TiO_2
Orthoclase	$KAlSi_3O_8$

I. J. R.—Ruthenium is practically insoluble in all acids and aqua regia. Its detection may be accomplished by fusion with potassium hydroxide and potassium nitrate, when the resulting K_2RuO_4, heated with NaCl in a current of chlorine yields soluble K_2RuCl_6. This greenish-black fusion gives with water an orange-yellow solution which stains the skin black.

F. J. T.—Your statement is incorrect. The natural coloring and essential oils of flower can be extracted by a cold process and when so obtained make an excellent toilet water or mouth wash. The cost of production, aside from the flowers themselves (which cost is little in certain seasons), is quite small, and no alcohol is required as a preservative.

F. S.—A chemical analysis is by no means a working formula; the first simply states the general composition, while the latter gives detailed instructions as to the commercial production.

Forward me the product and I will reproduce it and supply the working details within a week.

J. W. K.—I am sending you by mail the complete chemical analysis of the medicine labeled "CACHETS." This is used principally for locomotor ataxia, and since it contains very powerful drugs, I strongly advise you to consult a physician before using same.

G. F.—It will be necessary for me to charge you a small fee for the determinations of nitrogen in the various samples of explosives you propose sending me, on account of the care involved and the special apparatus required. A half-ounce sample of each will be ample for these tests.

Charles B. Davis.

Those whose inquiries to this department have not as yet received attention must bear in mind that unless replies by mail are specifically requested, communications can only be considered in the order of their receipt.—Editor.

EDITORIAL COMMENT

1918

The coming year promises to be the most critical in the history of our country. It will see the American nation enlisted in the Titanic world struggle as its most powerful factor. All eyes are turning in our direction. Of the the ultimate outcome of the conflict there can be no doubt. But it depends upon the efforts of the American people, during 1918, to demonstrate this fact so forcibly and clearly that our foes will realize the utter hopelessness of continuing further the terrible expenditure of blood and treasure, and the uselessness of prolonging the indescribable misery in which so many millions in Europe and Asia are despairingly plunged.

This year applies the acid test to American bravery, fortitude, resoluteness and resourcefulness. The efforts which we will put forth are bound to insure the coming generations of our nation from all danger of attack by a highly organized militaristic empire, unscrupulous in its methods, pitiless and remorseless in its viewpoint. But they will accomplish far more beyond our own borders in bringing that same assurance to the other nations of the world accepting the same standards of duty, of humanity and of civilization.

Every additional accomplishment on our part, shortening the war by a single day, is equivalent to lessening by millions the world's indebtedness, to saving thousands of lives, to ending a day sooner the enormous sum of physical and mental suffering, enveloping as a grim pall scores of millions of our fellow beings.

The year 1918 will demand the maximum of resolute, strenuous effort, as well as of prompt and cheerful sacrifice, on the part of every class and category in our population.

To the chemists of this land the demand comes with greater insistence than probably to any other class, for the war is emphatically a contest of chemists and engineers.

Our chemists are responsible for the quality and the prompt output of the munitions consumed in such huge quantities. We depend upon them to assure the fertility of our fields, now so heavily taxed, to assure the quality and supply of the iron and steel and other metals used in the manufacture of arms, to provide the drugs and supplies for a vast hospital service, the gases and liquid fire for trench warfare, to facilitate the conservation of our food supply.

At every step the chemist is directly or indirectly an indispensable cog in the gigantic military machine which we are forced to organize, so contrary to the inclinations and ambitions of a powerful but peaceful people.

Well may we be proud of what American chemists have accomplished during the past three years in solving purely economic problems. With far greater pride shall we look back upon their achievements at the end of the war, realizing to what an extent the final result will be due to their individual and combined efforts.

The German Dye Trade After the War

German economists are devoting an increased amount of attention to the problems facing the Empire's foreign trade relations at the close of the war. It is felt that every possible preparation must be made to reestablish the manifold commercial ties which connected Germany, four years ago, with the rest of the globe.

The stocks of foreign raw materials in Germany have long since been exhausted, and it will involve the expenditure of vast sums to secure needed supplies from every quarter to set the wheels of industry again in normal and continuous motion. The financing of this trade movement will evidently be a serious problem. If the heavy gold reserves of Germany can be utilized for this purpose, it would simplify conditions. That is, however, not probable, in view of the enormous issues of paper money, now in circulation; and based upon the relatively small amounts of metallic reserves in the banks. The great importing houses trust to a renewal of their former widespread connections in foreign lands, and a revival of the credit formerly existing, which would lead to a better regulation of payment and a distribution over longer periods of time. The extent of this credit is, however, of a very uncertain nature, and it unquestionably is lessening with every additional week of warfare.

The strongest emphasis is laid upon the export of products made from German raw materials. In this category stand prominently artificial dyestuffs and potash. It is regarded as highly desirable that the coal-tar color industry, now devoted largely to the manufacture of munitions, should be switched back to its normal activities, at the first signs of peace. By pushing to the utmost the sale of its products in all countries, it is hoped that credits can rapidly be established which will facilitate the purchase on a vast scale of the various textile fibres, the caoutchouc, the many tropical products, the hides and skins, the tin, the copper, oils and all the other supplies required by Germany's highly diversified industries.

In this plan there are, however, many factors of uncertainty. The dyestuff industries of Great Britain, France, the United States and Japan are being rapidly perfected. The domestic demands in these lands are being met with constantly increasing degrees of satisfaction as regards quality, variety and quantity. Exportation of dyes to other lands has begun on a modest but promising scale.

In our own country, a year hence, the field will be occupied so thoroughly that it is extremely doubtful whether any material amount of German colors can find a ready sale. Quite a number of the costlier colors, consumed in relatively limited quantities, will certainly be sought with eagerness. But it is questionable whether the German dye manufacturers to-day could sell over a quarter of the product which four years ago they shipped to the United States. In European countries and their colonies, for sentimental reasons, the proportion may be even less. Should the war continue for two or three years longer, the possibilities of recovering the lost trade will shrink to small dimensions.

Much the same may be said as to the reliance on German potash for a rapid recovery of foreign credits. In every part of the world efforts are being directed to utilize the varied potash occurrences, individually of restricted value, representing in the aggregate, however, enormous amounts.

Numerous economic organizations have been formed in Germany during the war, in which the purchase of supplies has been centralized and this has done much to prevent prices from rising to extravagant figures. It is doubtful whether their activities will cease at once with the arrival of peace. Powerful syndicates for controlling sales, especially in the export trade, existed before the war. They will undoubtedly be strengthened in the effort to recover the Empire's lost trade. The consolidation of the great dyestuff companies for this very purpose, is the most striking illustration of what will be the general commercial policy of Germany.

The American Color Industry

What better proof of the substantial growth of the American coal-tar color industry can be asked than that afforded by the extent of our exports of artificial dyes for the third quarter of 1917? The value of these exports for the three months was $1,173,439. This is equivalent to an annual export of about $4,700,000. Assuming that prices are five times the pre-war rates, we can claim to have reached the point where we can ship abroad, annually, coal-tar colors worth $1,000,000, while meeting the bulk of domestic demands, as compared with annual imports prior to the war valued at $10,000,000, and a domestic output (made from foreign intermediates) valued at about $3,000,000.

The figures are eloquent! We are still far from producing the variety of synthetic colors which our dyes need, but as far as quantity goes the industry is certainly on a very stable basis, and twenty-one foreign countries are securing supplies from us.

The National Synthetic Company, Fords, N. J., has awarded a contract for the construction of three new additions to its chemical manufacturing plant.

American Color Manufacturers Agree to "See It Through"

The Benzol Products Company.

The Benzol Products Company has surrendered its charter and ceased to exist as a separate corporation. This act is a natural sequel to its entry, last summer, into the general merger, constituting the National Aniline and Chemical Co., Inc.

The Company was organized in 1910 by representatives of the General Chemical Co., the Barrett Co., and the Semet Solvay Co.

It successfully established the manufacture of aniline on a large scale in this country, and has been a powerful factor in supplying large quantities of aniline and other coal-tar intermediates to our color industry during the past two years of expansion.

The Export of American Chemical Products

The outward movement of American chemicals has steadily grown during 1917. For the month of September the increase was from $15,344,000 in 1916 to $16,415,000 in 1917.

For the first three quarters of the year comparative figures are as follows:

1915	1916	1917
$54,056,000	$121,085,000	$141,204,000

There seems to be no question but that permanent markets are being steadily gained by American manufacturers in all parts of the world, from which it will be difficult to dislodge them when international exchanges are resumed.

The matter of chief importance, in the meantime, is to so assure the quality of American chemicals that they may be regarded in foreign countries as absolutely reliable in regard to purity and strength.

Neglect in this respect, here and there, on the part of a few careless exporters, may have disastrous results for the entire industry.

The Badische Co. of New York

This company, representing in the United States the famous Badische Anilin-und Soda-Fabrik of Ludwigshafen on the Rhine—known familiarly as "the Badische"—is now superseded by a new organization, Kuttroff, Pickhardt & Co. The latter takes over the entire staff of its predecessor, with its laboratories and branch agencies in Boston, Providence, Philadelphia, Chicago, San Francisco, Goldsboro and Montreal. The new designation recalls the original name of this great distributing agency before it was incorporated as "The Badische Co."

It is probable that sound business reasons dictated the dropping of the recent title, so distinctly German in its associations. The same reasons, with equal probability, caused the recent formation of the Century Color Co., which absorbed the technical and sales staff of the Cassella Color Co. of New York.

THE DETECTION OF RESIN IN DRIER

By E. W. Boughton*

In the Following Paper the Writer Tells How a Method Was Developed for the Detection of Resin in Driers Which Is Reliable Except When the Resin Content Is Very Small, for Example, Less Than Six Per Cent. of the Ash-Free Non-Volatile Portion.

INTRODUCTION.

In the preparation of paint by the painter a drier is added to hasten the drying. Common practice is to add about 5 parts by volume to 95 parts of oil. Commercial driers show on analysis from 2 to 10 per cent. of ash, containing lead, manganese, and sometimes calcium, and from 60 to 95 per cent. of volatile thinner, usually consisting of turpentine, mineral spirits,[1] or a mixture of the two. In addition to the above, what is known as "oil drier" contains linseed oil but no resin, while "japan drier" contains both linseed oil and resin.[2] This distinction, however, is not strictly adhered to in the paint trade. Sometimes oil driers and japan driers are sold under other names, and there are also on the market many special and patent driers which are not used for general painting work. The resin is added to the drier to prevent precipitation of metallic soaps after thinning and to decrease the tendency of the drier to "curdle" with oil. Oil driers are made, however, containing as much as 95 per cent. of mineral spirts, which contain sufficient lead and manganese to show satisfactory drying properties in laboratory tests.

The usual laboratory examination of driers includes the determination of the amount and nature of the volatile thinner, the amount and nature of the ash, a qualitative test for rosin, and drying tests with linseed oil. Purchasers of oil driers presumably desire material that is free from resins, and therefore a method for the detection of resin is needed.

THE SIGNIFICANCE OF RESIN IN DRIER.

The following statement appears in "One Thousand More Paint Questions"[3]:

> Japan driers differ from oil driers in so far as the first named are composed of gums or resins fused with linseed oil and driers such as litharge, red leaf, and manganese salts. * * * Oil driers are, or should be, used for oil paints for exterior work, because, being free from resinous substances, they tend less to the cracking of paint than the excessive use of japan driers, while on the other hand the latter should be employed where quick drying, as in flat or semiflat paints, is an absolute necessity and where surfaces are not exposed to severe weather conditions.

This statement probably expresses the ideas of those who prefer oil drier. The condemnation of "the excessive use of japan driers" is undoubtedly justified, but it is highly improbable that the small amount of resin introduced into a paint by the addition of 5 per cent. of japan drier would have any bad effect for outside paints. On the contrary, Dubois[4] showed that the addition of small amounts of "kauri mixing varnish" to linseed oil produced a vehicle that was superior to pure linseed oil for paints for iron and steel, the films being less pervious to water vapor and other gases. Toch,[5] in a summary of the results of exposure tests of painted steel plates on which different vehicles were used, includes spar varnish and a mixture of spar varnish and "stand" oil[6] in the class which showed "a high degree of protection against corrosion." The general use of spar varnish for exterior work on metal and wood and the practice of adding spar varnish to paint vehicles indicates that the presence of resin, when the amount is not excessive, is beneficial.

In answer to an inquiry from the Bureau of Standards, several manufacturers of driers gave their opinions regarding the classification and relative values of oil drier and japan drier. All stated that while the distinction between the two as given above is technically correct it is very frequently disregarded, and that while the amount of oil drier that is made and sold is considerable it is small in comparison with the amount of japan drier that is used. Only one manufacturer claimed that oil drier is preferable to japan drier, his statement being as follows: "Except for certain purposes a high-grade oil drier is to be preferred to a kauri japan drier." The same manufacturer stated that if rosin is present in a drier, the amount should be limited. With this exception, no manufacturer stated that the presence of rosin or mineral oil has any bad effect. One manufacturer called attention to the fact that driers (called by him "resinate driers") are used, the non-volatile organic portion of which is composed entirely of resin.

Ordinarily the judicious use of japan drier will introduce from 1 to 2 per cent. of resin into a paint and there appears to be no proof or general agreement among paint technologists that this small amount has any bad effect. It is improbable that its presence or absence makes any noticeable difference in painting results.

---

[1] The term "mineral spirits" is being generally accepted for the petroleum distillates that are used as substitutes for turpentine.

[2] In the paint trade the resins, other than rosin, are called "gums."

[3] Published by The Painters' Magazine, New York (1908).

*Associate Chemist U. S. Bureau of Standards. From a Technologic Paper published by the Bureau.

[4] J. Ind. Eng. Chem., 5, p. 968 (1913).

[5] J. Ind. Eng. Chem., 7, p. 510 (1915).

[6] Linseed oil, heated and allowed to stand in tanks for three to four weeks.

Although very good spar varnishes are made which contain small amounts of rosin, the presence of a large amount in a paint vehicle makes the latter unsuitable for outside work, and since no data are available to show the maximum amount which may be present without lowering the quality, specifications for driers and for outside varnishes almost always prohibit the use of rosin.

EXPERIMENTAL.

Preparation and Collection of Samples.

The composition of the driers used in this investigation is shown in Table 1. The sample designated as No. 1 was prepared from linseed oil, litharge, manganese dioxide, and turpentine; No. 2 from these materials and kauri. Nos. 3, 4, and 5 were prepared from linseed oil, litharge, and manganese dioxide, no thinner being added. After all the oxides had been added to the heated oil, the mixtures were heated at 250-300° C for one-half, one, and two hours, respectively. Nos. 6, 7, and 8 were made in the same way as were Nos. 3, 4, and 5, except that red lead was substituted for litharge and the samples were thinned with turpentine. Seven more samples, Nos. 9 to 15, inclusive, were prepared from various resins and oils, manganese dioxide, lithrage, and turpentine, the mixtures of oil, resin, and oxides being heated for one hour at 250-300° C. Nos. 16 to 39, inclusive, were obtained from manufacturers[7], the data regarding the composition of these samples being compiled from the statements of the makers. In the preparation of commercial driers, the mixtures of oil, resin, and metallic compounds are heated for so long a time and at so high a temperature that the percentages of oil and of resin in the finished driers can be only approximately estimated.

Preliminary Experiments.

Rosin can be detected, of course, by the well-known Liebermann and Storch test with acetic anhydride and sulphuric acid. Attempts to identify and detect other resins by the color test of Hicks[8] were not successful. Determination of the acid number of the mixtures of unsaponifiable matter, fatty acids, and resin acids, obtained from the driers by saponification and subsequent treatment with acid, was found to be useless as a means for the detection of resin, because prolonged heating during the preparation of oil drier lowered the acid number very much. For instance, the mixtures of unsaponifiable matter and fatty acids obtained from Nos. 3 and 5 (heated for one-half and two hours, respectively) showed acid numbers of 186 and 165, respectively.

Detection of Resin by the Alcohol Method.

The mixtures of unsaponifiable matter, resin acids, and fatty acids, obtained from the driers as stated above, were treated with ethyl alcohol of two strengths, 95 and 97 per cent. by volume. In most cases the samples containing resins other than rosin showed a marked turbidity or a deposit of insoluble matter. It will be noted from the results of these tests, as shown in Table 1, that to obtain clear solutions with Nos. 6 to 8, inclusive, it was necessary to use 97 per cent. alcohol. With these samples the use of 96 per cent. alcohol gave solutions that were very faintly turbid. It will be noted also that by this method it was impossible to detect the presence of rosin, manila, shellac, and the very small amounts of kauri that were present in Nos. 34 to 36, inclusive.

TABLE 1

Detection of Resin by Alcohol Method

No.	Constituents other than thinner and metallic oxides		Name of drier given by manufacturer	Appearance of alcohol solution

Detection of Resin by Esterification and Subsequent Determination of the Acid Number.

The usual method for the determination of oil and resin in mixtures of the two includes esterification by Twitchell's[9] method, using absolute alcohol and dry hydrochloric acid gas, or by Wolff's[10] method, using absolute alcohol and concentrated sulphuric acid. Preliminary experiments with fatty acids prepared from linseed oil, the results of which are shown in Table 2, showed that more nearly complete esterification was obtained by the former method, absolute ethyl alcohol being used. As is also shown in Table 2, variation of from two to five minutes in the time of heating in the Wolff method did not affect the results obtained with the mixtures of acids and unsaponifiable matter from oil drier and japan drier. The Wolff method is shorter and simpler than the Twitchell method, and the results obtained with various samples of driers, as given in Table 3, show that as a qualitative test for resin the former is satisfactory. The maximum figure for acid number after esterification was 9 for oil driers and the minimum figure for japan driers was 11. Since the figure obtained with No. 34 is within experimental error of the maximum figure for oil drier, the method can not be depended upon to detect less than 6 per cent. of resin in the ash-free nonvolatile portion of a drier. This is ordinarily equivalent to a resin content of less than 3 per cent. in a thinned drier ready for use. The figures obtained with driers are given as whole numbers because the end point of the titration, using phenolphthalein as indicator, was so obscured as to cause a possible error of 0.1 cc of 0.25 N alkali. This would result in an error of 1.4 in the acid number determined with a 1 g sample. In fact, an accuracy of two in the determination of acid number is all that can be expected. Samples that weigh over 1 g can not be used since the solutions would then be too dark in color.

PROPOSED METHOD FOR THE DETECTION OF RESIN IN DRIERS.

(1) Test for rosin by the Liebermann and Storch method with acetic anhydride and sulphuric acid.

(2) If no rosin is detected by (1), place about 25 cc of the drier in a flask and pass in a rapid current of steam while heating the flask in an oil bath at 130° C. Add an excess of alcoholic potash, and heat on the steam bath for one hour. Add an excess of hydrochloric acid and shake vigorously. Fill the flask with hot water and allow the oily layer to collect in the neck of the flask. Remove about 5 cc of this oily layer to another flask, add about 25 cc of dilute hydrochloric acid (1:1), and boil for a few minutes. This is necessary to insure the decomposition of all metallic soaps. Cool, add about 20 cc of ether and sufficient water to bring the ether solution into the neck of the flask. Filter a portion of this ether solution into a flask, evaporate off the ether, and dry the residue at 110-115° C for one-half hour. Place 0.15-0.20 g of this residue in a test tube, add 5 cc of ethyl alcohol (97 per cent. by volume), and shake. A turbidity or a deposit of insoluble matter shows the presence of resin in the sample.

(3) If no resin is detected by (1) or (2), filter into a tared flask a sufficient amount of the ether solution obtained in (2) to yield a dry residue of 0.8—1.0 g. Evaporate and dry as stated under (2) and weigh the flask and dried residue. Add 10 cc of absolute ethyl alcohol, warm gently till the solution is clear, and add a mixture of 10 cc of absolute ethyl alcohol and 3 cc of concentrated sulphuric acid. Boil under a reflux condenser for two or three minutes, cool and transfer the contents of the flask to a separatory funnel, washing out the flask with water and ether. Add 25 cc of a 10 per cent. solution of sodium chloride and shake. Draw off the lower layer and shake it with 50 cc of ether. Unite the ether solutions and wash with water until the washings are neutral. Three washings will usually suffice. Transfer the ether solution to a large flask and dilute with neutral 95 per cent. alcohol until the color of the solution is sufficiently light to permit of titration with 0.25 N alcoholic potash, using phenolphthalein as indicator. Dilution to 400—600 cc is generally necessary. If the dilution with alcohol causes a turbidity, add sufficient ether to clear the solution. Titrate with 0.25 N alcoholic KOH and calculate the acid number as milligrams of KOH per gram of the mixture of unsaponifiable matter and acids taken. An acid number of over 10 shows the presence of resin in the sample.

SUMMARY.

A method has been developed for the detection of resin in driers which is reliable except when the resin content is very small, e. g., less than 6 per cent of the ash-free nonvolatile portion.

RELATION BETWEEN COMPOSITION AND DENSITY OF AQUEOUS SOLUTIONS OF $CuSO_4$ AND H_2SO_4

By H. D. Holler and E. L. Peffer[*]

INTRODUCTION.

In connection with an investigation on the regulation of solutions for electrodeposition, especially of acid copper sulphate solutions for electrotyping, it was found desirable to devise a simple method of determining and adjusting their composition. Since the solutions usually employed for the above purpose contain only copper sulphate and sulphuric acid, the composition of any given solution is fixed if the acid content and density at a given temperature are known. The density can be readily determined with a hydrometer, and the acidity can be ascertained with sufficient accuracy by titration with standard alkali, using methyl orange as indicator, as described by Wogrinz.[1] In order, therefore, to learn the content of copper sulphate, all that is required is a table showing the density of solutions containing known amounts of copper sulphate and of sulphuric acid.

Although the densities of solutions of copper sulphate and of sulphuric acid have been determined separately, no systematic study of the densities containing both could be found in the literature. Only in isolated cases were such data given concerning certain baths, such as those recommended by Pfanhauser,[2] Langbein-Brannt,[3] Steinach and Buchner,[4] and others.

The concentration of solutions containing both copper sulphate and sulphuric acid is limited by the fact that addition of sulphuric acid to copper sulphate solution causes a marked decrease in the solubility of the copper sulphate. Thus, while 395 grams of crystallized copper sulphate is contained in 1 liter of the saturated solution at 15°C, the addition of 100 grams per liter of sulphuric acid reduces the solubility of the copper sulphate to 215 grams per liter. Since in any practical work it is necessary to use solutions somewhat removed from the saturation point, the actual field is probably included in the range of 0 to 20 per cent of each of the constituents. Such solutions, therefore, formed the basis of this investigation. The temperature range of 25° to 40°C was selected as including the normal temperature employed in most copper plating or refining operations. Doubtless the expansion coefficients determined from such data will permit extrapolation over a moderate range above and below the temperatures used.

METHOD OF INVESTIGATION.

Preparation of Solutions.

In order to avoid the influence of temperature in the preparation of the solutions, they were all made of a known composition by weight, expressed in grams of each constituent per kilogram of solution. They were prepared in duplicate by mixing accurately weighed portions of water and of standardized concentrated solutions of copper sulphate and of sulphuric acid.

The stock sulphuric acid solution was prepared by diluting c. p. acid to about 12 normal with distilled water, and was standardized by the barium sulphate method with the usual precautions. It was also compared with a hydrochloric acid solution, standardized by silver chloride precipitation, through a solution of sodium hydroxide, using methyl orange as indicator.

The concentration of the sulphuric acid solution as determined by the barium sulphate method agreed with that obtained by comparison with the standard hydrochloric acid solution to within about 1 part of 1500. Weight burettes were used, the individual titrations agreeing to within less than 1 part in 2000.

The solution of copper sulphate was prepared from recrystalized salt, which gave a perfectly clear solution. The concentration of copper sulphate ($CuSO_4$-$5H_2O$) was calculated from the copper content determined electrolytically, the greatest difference between any two results being 1 part in 3000. Complete removal of copper from the electrolyte was confirmed by testing with $K_4Fe(CN)_6$.

Density Determination.

Method of Determination.—The density measurements were made by the method of hydrostatic weighing, i. e., by weighing in the sample under investigation a sinker of known mass and volume. The density[5] of the liquid is then calculated by means of the equation:

$$D_t = \frac{W - \dfrac{(w - w_1) + (w - w_2)}{2}\left(1 - \dfrac{p}{8.4}\right)}{V_t}$$

[a] All densities here tabulated are expressed in grams per milliliter.
[b] Change in density per degree rise in temperature.
[c] Solutions of these compositions do not exist at 25° C.
[d] Sample lost by breakage of the container.

The densimeter tube (about 45 cm long and 2.5 cm in diameter) containing the sample is placed in a water bath which is kept in constant circulation. This bath is surrounded by another, also in circulation, the temperature of which is regulated by means of an electric heating coil and a brine cooling coil. The temperature of the inner bath is determined by the use of two mercury thermometers. The large sinker having a length of approximately 33 cm and diameter of 1.3 cm is attached below a small sinker and both are suspended by means of a wire from one arm of a sensitive balance. The small sinker which is in the liquid at all times serves the purpose of keeping the suspension wire taut and in position, and thus the effect of surface tension is eliminated.

Method of Making Observations.—After sufficient time has elapsed for attaining temperature equilibrium at the desired temperature, the first weighing is made with the large sinker attached, and the temperature is immediately read from each of the thermometers. Then the second weighing is made with the large sinker detached from the small sinker. In order to obviate any correction for a possible change in temperature, the first weighing is repeated and the thermometers reread. The average of the temperatures at the two weighings is taken as the true temperature. The difference between the mean of these two weighings and the second weighing is the apparent weight of the large sinker in the sample at the given temperature. After completing the observations at one point, the temperature is changed to the next and the process is repeated in the same order.

RESULTS OF INVESTIGATION.

The results of the density determinations and composition of the samples are shown in Table 1.

In Table 1 the composition of the solutions is expressed in grams of $CuSO_4.5H_2O$ per kilogram of solution. The concentration in grams per liter may be readily obtained by multiplying the above concentrations in grams per kilogram by the corresponding densities. In each case density determinations were made upon duplicate solutions, and these results are seen to agree in most cases to somewhat better than 1 in the fourth decimal place. From the density data for 25° and 40° C, respectively, the thermal density coefficient *a* has been calculated, which may be defined as the change in density (always negative) for an increase in temperature of 1° C.

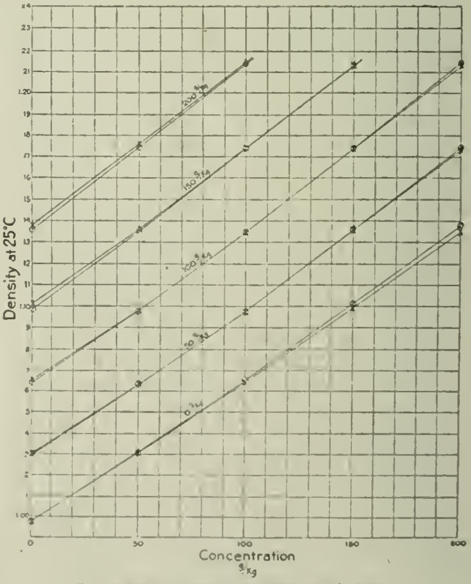

FIG. 1—D[illegible] of copper sulphate-sulphuric acid solutions.
O—Sulphuric acid constant
X—Copper sulphate constant

The above results are shown graphically in Fig. 1, which illustrates the effect upon the density of additions of copper sulphate to sulphuric acid solutions and of sulphuric acid to copper sulphate solutions. The curves for sulphuric acid solutions are derived from the data of Domke as given in Landolt and Börnstein, fourth edition (1912). The close agreement between the densities of solutions of the same total concentration, shown in Table 2, is illustrated in Fig. 1. The curves passing through the circles show the change in density produced by the addition of copper sulphate to solutions containing a definite amount of sulphuric acid per kilogram of solution. Those through the crosses show the change in density produced by the addition of sulphuric acid to solutions containing a definite amount of copper sulphate per kilogram of solution, the total concentration in each case being the same as for the corresponding curve through the circles.

Example.—In the case of the curves marked 50 g/kg, the one passing through the circles shows the change in density produced by the addition of definite amounts (50, 100, 150, 200 grams) of copper sulphate to a solution containing 50 grams of sulphuric acid per kilogram of solution, and the one passing through the crosses shows the change in density produced by the addition of the same definite amounts of sulphuric acid to a solution containing 50 grams of copper sulphate per kilogram of solution.

TABLE 2

Showing the Relation Between Total Concentration and Density

Total concentration, g/kg	$CuSO_4\cdot5H_2O$, g/kg	H_2SO_4, g/kg	Density, 25° C
50	0	50	1.0300
	50	0	1.0302
100	0	100	1.0640
	50	50	1.0630
	100	0	1.0646
150	0	150	1.0994
	50	100	1.0984
	100	50	1.0983
	150	0	1.1006
200	0	200	1.1365
	50	150	1.1355
	100	100	1.1350
	150	50	1.1355
	200	0	1.1383
250	0	250	1.1751
	50	200	1.1742
	100	150	1.1737
	150	100	1.1736
	200	50	1.1749
300	0	300	1.2150
	100	200	1.2140
	150	150	1.2139
	200	100	1.2145

From the above tables and curves it may be seen that—

1. Within the range studied, the density of copper sulphate-sulphuric acid solutions is approximately a linear function of the concentration.

2. The density of solutions of equal (not equivalent) concentrations of copper sulphate ($CuSO_4.5H_2O$) and of sulphuric acid is nearly identical.

3. As a natural consequence of the conclusions noted in (1) and (2), a curious relation was found to exist, i. e., that the density of solutions containing appreciable amounts of each constituent is dependent principally upon the total concentration of the two solutes, and is almost independent of their proportion. (See Table 2.) Thus, a solution containing 50 grams per kilogram of copper sulphate and 150 of sulphuric acid has practically the same density (1.1355) as has a solution containing 100 grams per kilogram of copper sulphate and 100 of sulphuric acid (1.1350). This simple relation which is apparently only a mathematical coincidence, has been used as the basis for the curve shown in Fig 2

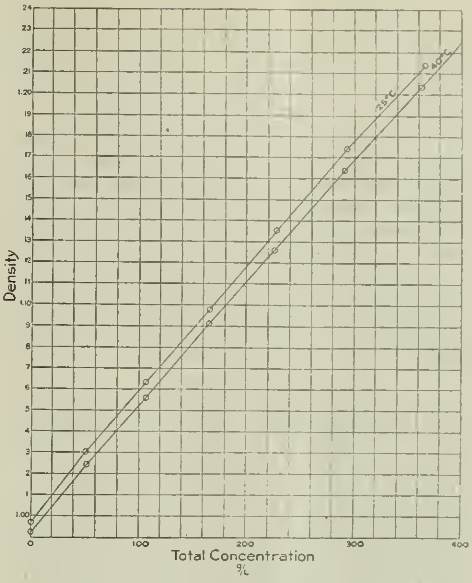

FIG. 2.—*Density of solutions of total concentration of copper sulphate plus sulphuric acid*

in which the total concentration, in grams per liter,[6] of copper sulphate plus sulphuric acid is plotted against the density, yielding an almost straight line. The application of such a curve, or of the table derived from it (Table 3), in determining the composition of unknown solutions, is obvious, involving only a determination of the density and acidity, the latter then being deducted from the total concentration corresponding to the observed density, to obtain the copper sulphate concentration.

Details of the application of this table in the regulation of electrolytic copper baths will be given in the second edition of Bureau of Standards Circular 52.

This work was carried out under the direction of Messrs. W. Blum and H. W. Bearce.

"Cost Accounting for Oil Producers."

The Bureau of Mines, Department of the Interior, has recently issued Bulletin No. 158 on "Cost Accounting for Oil Producers," by Clarence G. Smith. This is the first treatise of its kind and is a simple explanation of the methods that may be employed in cost accounting for oil producers, who, on account of the peculiar and unusual conditions affecting oil production, require a much different system of cost accounting than any other class of business men.

When the principles of accountancy are applied to any business the accounts and bookkeeping methods employed naturally depend on the character of the business, and even though several businesses may be similar in character, the accounting may be varied to suit the conditions peculiar to each when the problems encountered are not uniform. Therefore, in order to plan and carry out the accounts and bookkeeping system best adapted to a particular business, the accountant must study not only local problems, but also the details of the business at large.

Mr. Smith says in part:

"Prior to the actual development of an oil property it is difficult to determine the quantity of oil under the property and the rate at which this oil can be brought to the surface-factors that determine the ultimate value of the property. Consequently there has been much confusion in devising accounting systems that, during the entire life of a property, will show costs and profits from which the producer can determine whether his property is being worked at a profit or otherwise. The Bureau of Mines publishes this report in recognition of a distinct need for a simple treatise on accounting methods adapted to the peculiarities of the petroleum industry.

"Probably many companies operating oil wells are not fully acquainted with details important to the welfare of their business, because their account books fail to furnish them with exact and adequate data.

"With the accountant rests the responsibility of providing the management with reports setting forth the details of the business expressed in fitting terms as well as in dollars and cents. These reports are a means whereby efficiency may be maintained, waste prevented, oil obtained and sold, and money suitably reinvested. They also enable a concern to study the progress of its business in order to conserve to the utmost hte possible benefits from an exhaustible deposit of mineral wealth. When managements realize the extent of the waste at their properties more attention will be given to the character of the accountancy records."

The treatise gives descriptions and discussions of balance sheets, profit and loss statements and bookkeeping methods peculiarly adapted to the oil business. As far as possible, technical phrases have been omitted in order that those not familiar with accounting terms may be able to follow the subject matter. All the systems of keeping books outlined have been found practical and have been in actual use in some particular oil field. The writer has recognized that local differences in field practices exist and has sought to present accounting methods that provide for such differences.

This publication may be obtained free of charge by application to the Director, Bureau of Mines, Washington, D. C.

Dr. Arthur H. Elliott.

Dr. Arthur H. Elliott, 68 years old, formerly a professor of chemistry at Columbia University and chief of the chemical department of the Consolidated Gas Company, died Feb. 28 of Bright's disease, in the Peekskill Hospital, Peekskill, N. Y. Dr. Elliott was born in London, England, was educated there, and after graduation from the British School of Mines in 1879 came to the United States. He completed his educational course in chemistry at Columbia University in 1881, specializing in gases, which brought him his position later with the Consolidated Gas Company. Dr. Elliott was a member of the Engineers' Club, the University Club, the Chemists' Club and the Fireside Club, of Peekskill, N. Y. He lived at 284 Washington place, Flushing. His widow was the daughter of the late Dr. James Uglow. He also is survived by three daughters.

Chemical Clay Products Co.

The Chemical Clay Products Co., Daisy, Tenn., has been incorporated with a capital of $50,000 by L. E. and B. M. Hood, and G. S. Keeling.

---

[6] Obviously, the above relation exists whether the concentration is expressed in grams per kilogram or grams per liter. The data shown in Fig. 2 and Table 3 have been calculated to grams per liter since the results of the analysis of solutions are usually expresed in that form.

DEFERRED CLASSIFICATION FOR CHEMISTS OF DRAFT AGE

Owing to the disturbance in many essential industries on account of important men being drafted, government instructions have been issued relative to deferred classification for chemists. The letter and blank forms "B" and "C" shown on the following page are self-explanatory.

It should be borne in mind that these applications for exemption should be used only in cases where the employee is absolutely necessary for the practical operation of a plant or factory.

It is not necessary to secure copies of blank forms "B" and "C." Simply make a typewritten copy of the forms as shown. In copying the forms sufficient space should be left under each question to accommodate the answer; therefore a longer sheet should be used than shown in the copy. The answers should be filled in with typewriter, using a different colored ribbon.

Form "B" is for chemists who are in the draft, and *not* in the Army or Naval Service.

Form "C" is for chemists who are at present in the Army or Naval Service.

The forms when filled out should be addressed to "Chief of Chemical Service Section, N. A., New Department of Interior Building, Washington, D. C."

How to Proceed.

Below follows a letter from Lieutenant-Colonel William H. Walker, Chief, Chemical Service Section, National Army, outlining the procedure to be followed in such cases:

Office of the Chief of the Chemical Service Section, N. A.
1106 New Interior Building,
Washington, D. C.

By an order of the Secretary of War, the Adjutant General of the Army has authorized the Chief of the Chemical Service Section of the National Army to initiate such measures as are necessary to secure deferred classification for chemists whose services are essential to war industries. Under the Selective Service Regulations such action is limited to a letter of advice to the Local and District Exemption Boards transmitted through the Adjutant General's office, substantially as follows:

> "The Chemical Service Section of the War Department has investigated the status of your company in connection with the production of war material and considers it important that the efficiency of your organization be maintained. In this connection the services of .... as a technical expert in .... have been investigated and it is believed that his continued employment in war industries would be to the best interests of the Government. You are therefore advised to apply to the local exemption board for deferred classification in his case on the ground that he is a necessary highly specialized technical expert of a necessary industrial enterprise. Such action, of course, should be taken only with Mr.. .... .'s consent. If he prefers to enter the military service, please advise this office of that fact in order that his services may be utilized where most needed."

Under the same order of the Secretary of War the Chief of the Chemical Service Section will initiate action for the return to civil industries of any expert chemist whose service in the industry from which he was taken is of more importance to the Government than are his services in a military capacity. He must certify that the man is considered indispensable in industry or that his services are essential to the prosecution of the war, and that his place cannot be filled by a man or woman not in the Army. Except in the cases of members of the Reserve Corps, the action taken will consist of a recommendation to the Adjutant General of the Army that the man concerned be discharged from the National Army, National Guard or Regular Army, as the case may be, re-enlisted or recommissioned in the proper branch of the Reserve Corps, and placed on the inactive list. In the cases of members of the Reserve Corps the action will consist of a recommendation that the man concerned be placed on the inactive list.

The Secretary of War further directs that upon the transfer to the Enlisted Reserve Corps for this purpose the enlisted man so transferred will be directed to report to the employer who requires his services. The employer in each case will be advised of the man's transfer for the specific purpose intended and will be requested to report to the Department Commander at the end of each month the status of the soldier, and should at any time the soldier separate himself from such employment, the employer will immediately notify the Adjutant General of the Army of such separation and, if practicable, the latest address of the man.

The forms "B" and "C" following indicate the proper method of requesting action—a separate application must be made for each man.

(Signed) WM. H. WALKER,
Lieut. Col., Chief, Chem. Ser. Sect., N. A.

FORMS "B" AND "C."

For the benefit of manufacturers who may desire to use them, these forms, issued by the government, are herewith reproduced. It is not necessary to send for blank copies; typewritten copies of these moy be made and the answers filled in using a typewriter ribbon of a different color. Forms should be addressed as indicated in the foregoing article. Read carefully all instructions as to their proper use.

EDITORIAL COMMENT

Industrial Reconstruction

War conditions are rapidly bringing about revolutionary changes in our economic fabric. With a stroke of the pen the country's many railway systems are consolidated into a unit. Fundamental price conditions for leading staples are regulated by centralized authority.

Much that is being done in order to ensure the victory of our arms, will cease when the victory is attained. Unquestionably, however, industrial relations during the coming years, after peace is proclaimed, will be radically modified. This fact has been promptly recognized by Great Britain, as the inevitable result of the experiences of the past three years. A national council for the Study of Industrial Reconstruction has been actively at work collecting ideas and suggestions. and has now embodied them in a report which formulates direct proposals for practical reconstruction.

The whole subject is one of importance to our American chemical industry and especially to the rapidly expanding coal-tar chemical branch. It seems desirable, therefore, to note in some detail the features of the British plans.

Essentially the scheme involves the establishment of a complete new system of trade government comparable to existing systems of local government, with a ministry at the head, controlling numerous trade councils with powers comparable to those of the existing county councils of Great Britain. It recognizes the essential principle that industrial interest should be grouped by trades, and not by localities. The preliminary manifesto of the Council is signed by a highly important and representative body of manufacturers and officers of employers' associations. It invites the workers cordially to join with the management in the self-government of industry, gives them an equal status and responsibility on the controlling body. The promoters of the movement attach importance to the support of the trade press.

The council proposes that British industries shall be developed on the following lines:

1. The mobilization of each industry for common action. 2. A greater degree of co-operation between manufacturers. 3. Co-operation between labor and capital, and the avoidance of industrial strife. 4. A more complete association between scientific institutions and traders. 5. Education better adapted to commercial needs. 6. Each industry to be studied as a whole, and freed from unnecessary internal competition. 7. Every trade to present a united front to foreign competition. 8. Output regarded as a duty by both capital and labor. 9. Encouragement by the Government of the activities of traders, with a minimum of interference.

It will be noticed that emphasis is placed upon an increase of output. During the war, so far, it has been necessary to adopt exceptional measures to secure a maximum output of munitions. It is now felt that such ideals must be kept constantly in view in perfecting future industrial relations.

The Council frankly recognizes that there has been a failure on the part of the Government to fully appreciate the importance of industry and commerce to the national welfare. It therefore makes the following suggestions:

(*a*) That a national organization should be established, which will retain all the sterling qualities of the present individualistic system and add to them the necessary ordered force to ensure greater activity; (*b*) that such an organization will need to provide for the representation of all classes of persons engaged in a given industry; (*c*) that industry should, therefore, be enfranchised, and every man and woman, employer and employed, given a vocational or trade vote, by means of which this representation would be effectively realized; (*d*) that every citizen should have the right to register with some approved trade association or trade union, and thus an Industrial or Vocational Register properly classified would be produced; (e) that trade councils should be elected in each industry from the trade associations and the trade unions, chosen upon a truly representative basis, able to speak in the names of the whole of their respective industries; (*f*) that all questions arising between the Government and a given trade should be delegated to the council of that trade, which would have power to deal with them; (*g*) that questions of output, education, trade schools, scientific research, export, wages, markets, tariffs, etc., should be settled in each trade by the council of that trade, and national funds, expended upon such matters should be dispensed through the trade councils.

A Government department would be established to promote or encourage trade, and should be assisted by an advisory council of the chairmen of the trade councils. As regards the trade councils, it is proposed that they shall be elected triennially, and consist of three classes of members—members elected by trades associations, members elected by trade unions, and members elected by the council on the nomination of Government departments.

The dominant feature in the scheme of industrial reconstruction is the basis of a vocational franchise. This renders possible the organization of each trade under a trade council in which labor and capital are both represented.

Such a scheme is essentially democratic in its nature. It should contribute enormously to increase the feeling of solidarity in a given industry, and to further the maintenance of amicable relations between employers and employees. In its entirety it would act as a balance wheel upon the general industrial movement, preventing excesses promoting good feeling and ensuring unity of action in a multitude of directions.

It is not difficult to picture the conditions under which our coal-tar chemical industry could expand, harmoniously and symmetrically, were it backed by such an organization. The problems of building up an export trade would be solved with much less of friction and much more of certainty Unnecessary duplication could be avoided in numerous connections. An intelligent and uninterrupted interest on the part of the Government would be assured.

The fundamental ideas worked out and formulated by our British cousins, under the strain of unprecedented conditions, are well worthy of careful study on this side of the ocean, and especially by those devoted to building up our chemical industries.

German Propaganda?

So many attempts to influence public opinion in this country, by suggestions and rumors of a nature to undermine unity of action and patriotic effort during the war, have been disclosed of late that we may well assume anti-American interests to be closely connected with the circulation of reports to the effect that the National Aniline and Chemical Company is controlled by German capital.

So persistent have these statements become in trade circles that the secretary of the company, Mr. W. T. Miller, has issued the following vigorous protest:

"Our attention has been directed to rumors now current to the effect that the National Aniline and Chemical Company, Inc., is under the control of German interests. Such statements, if made, are, in view of existing conditions, obviously so false that they are assumed to be malicious.

"The fact is this company is American owned and under American control, is operated by American chemists, and makes American dyes from American raw materials. It has brought together an aggregation of producing units under exclusively American control adequate to safeguard American consumers from the disastrous conditions forced upon the country at the inception of the war in 1914."

Mr. Miller intimates further that actions in damages may be instigated against persons circulating such reports.

While it is true that leading factors in the organization, the Schoellkopfs of Buffalo, and Dr. W. Beckers of Brooklyn, are of German origin, all who enjoy their acquaintance know that their American sentiments are of the most stalwart kind, and that they are devoted heart and soul to building up a genuinely American dyestuff industry. Interests adverse to the success of this effort are undoubtedly responsible for spreading the rumors in question.

Indanthrene Colors in England.

As an instance of the energetic effort now being made in England to firmly establish the manufacture of important vat dyestuffs, it is interesting to note that one of the minor factors in the industry, the Solway Dyes Company, Carlisle, are now producing, and in some cases have been producing for some time, the following Indanthrene dyes: Yellow G, Blue, Dark Blue, BO, Green B, Brown BB, Red BN, Pink B, and Violet R extra. Alizarin Sapphirol and Cyanine Green are also manufactured by the company, the former since March, 1916.

British Dyes, Ltd., is also rapidly extending its output of vat dyes, sold under the trade name of chloranthrenes, but essentially identical with the older indanthrenes.

In the case of both companies, the output is hampered by difficulty in securing adequate supplies of raw material.

THE EVOLUTION OF ARTIFICIAL COLORS*

The layman who has casually come into contact with synthetic color manufacture concludes instinctively that there must be a great variety of operations involved in an industry that deals with such complex compounds, and yields products whose number runs well into the thousands. The contrary is the case. Elementary materials are few in number, and equally few are the chemical and mechanical operations required to transform them into an almost endless variety of shades and tints.

Five Stages in the Evolution of Colors.

If we analyze the evolution of a synthetic color, the various stages are as follows:

1. Bituminous coal is submitted to destructive distillation.

2. From the volatile products of distillation, coal-tar is condensed and separated, and a few volatile hydrocarbons are recovered from the current of gas by passage through so-called benzol scrubbers.

3. The coal-tar is submitted to fractional distillation. Among nearly two hundred distinct chemical compounds present in the tar, some eighteen are isolated, possessing more or less value in the synthetic production of colors, medicines, explosives, flavors, perfumes and photographic developers. This total output is augmented by additions from the benzol scrubbers. Of the small group of useful constituents, of chief importance in the color industry are benzene, toluene, naphthalene, anthracene and phenol. The rest, including the three isomeric xylenes, pseudocumene, methyl-anthracene, phenanthrene, and the closely allied carbazole among the hydrocarbons, the three isomeric cresols, and the bases acridine, pyridine and quinoline, play minor although useful rôles.

4. The various coal-tar crudes, as these eighteen substances are termed technically, after being carefully purified, undergo complete transformation by treatment with a few chemicals. Through successive operations the chemist produces from them about three hundred so-called intermediates. These, with a few exceptions, are not susceptible of direct use in the arts. They serve simply as stepping stones.

5. One or more intermediates are submitted to a chemical reaction, bringing about combination or material alteration in molecular structure. The resultant product undergoes the necessary mechanical treatment—filtering, drying, etc.—and constitutes then a commercial ware.

We know but little of the exact combined forms in which carbon, hydrogen, oxygen and nitrogen are present in bituminous coal. Limited, also, is our knowledge of what takes place in a coke oven, as, under the influence of a high temperature, scores of different chemical individuals spring into existence. The initial stage is, therefore, one largely if not wholly of a mechanical nature. The same may be said of the second and third stages connected with the collection, separation and purification of the coal-tar crudes. It is in the fourth and fifth stages that the chemist dominates, and mechanical features assume a purely subordinate position.

In the fourth stage, the manufacture of intermediates, we encounter the great mass of perplexing difficulties. The German and Swiss companies engaged in this branch have mastered these difficulties, have coordinated all the multitude of accessory factors, scientific, technical and commercial. Herein lay the secret of their ability so largely to dominate the world's trade in artificial dyes. Through the thorny mazes of this chemical jungle are struggling, at this moment, hundreds of American coal-tar chemists, determined to achieve as complete a grasp of the complicated industry as their professional rivals on the banks of the Rhine.

Chemical Operations of Color Manufacture.

Nitration is perhaps the most frequent of all the operations involved in color manufacture, as well as the fundamental reaction in transforming coal-tar crudes into high explosives. An aromatic compound is subjected to the combined action of nitric and sulfuric acids. The strong affinity of the latter for water comes into play. The hydrogen and oxygen necessary to form water are extracted from the two associated substances. Nitric acid yields OH and the aromatic compound surrenders an atom of hydrogen, whose place is taken by the residue of the nitric acid molecule, NO_2. The extent and nature of the reaction are affected by the factors of time, temperature and proportions. Thus benzene can be transformed, at will, into mono-nitrobenzene or into any one of three dinitrobenzenes.

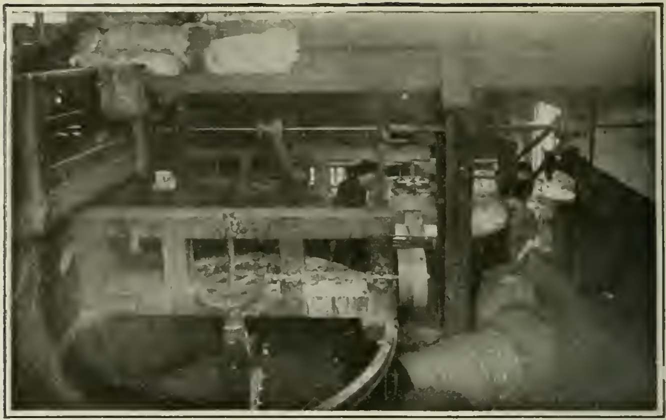
Reduction.—The oxygen in a nitro derivative may be replaced by hydrogen, and the corresponding amido compound thus formed. For example, benzene, C_6H_6 is changed by nitration into nitro-benzene, $C_6H_5NO_2$, and that, in turn, by reduction, into amido-benzene or aniline, $C_6H_5NH_2$. The reaction depends upon the liberation of hydrogen, which in the nascent state easily appropriates the oxygen atoms of the nitro group, introducing in their stead other hydrogen atoms. Iron filings or zinc dust with acetic, hydrochloric or sulfuric acid form the customary reducing agents.

Sulfonation is wholly simliar to nitration, strong sulfuric acid, and very frequently fuming sulfuric acid, being employed in place of nitric. The sulfo group,

---

*From the Scientific American.

DYE MIXING VATS IN OPERATION.



(Courtesy the Scientific American.)

SO_3H, replaces a hydrogen atom in the aromatic compound; thus benzene gives rise to benzene sulfonic acid, $C_6H_5SO_3H$. These derivatives are genuine acids; the hydrogen atom can be replaced by metals, ammonium groups, etc. Thus we have potassium benzene-sulfonate, $C_6H_5SO_3K$. Theoretically, at least, for every nitro derivative of an aromatic compound there is a corresponding sulfo derivative, and many of these are of great importance in the synthesis of valued dyestuffs.

Chlorination.—This term applies to the action of dry chlorine gas upon aromatic compounds. One half of the chlorine employed is recovered in the form of hydrochloric acid, HCl, the other half replaces hydrogen in the aromatic compound. The gas used for this purpose is obtained in connection with the electrolytic production of caustic soda from salt. It is liquified for transportation and allowed to volatilize as needed. The use of bromine and iodine in reactions similar to those of chlorination is limited.

Oxidation is frequently affected by the aid of bichromates, chlorates, permanganates, lead peroxide or managanese dioxide.

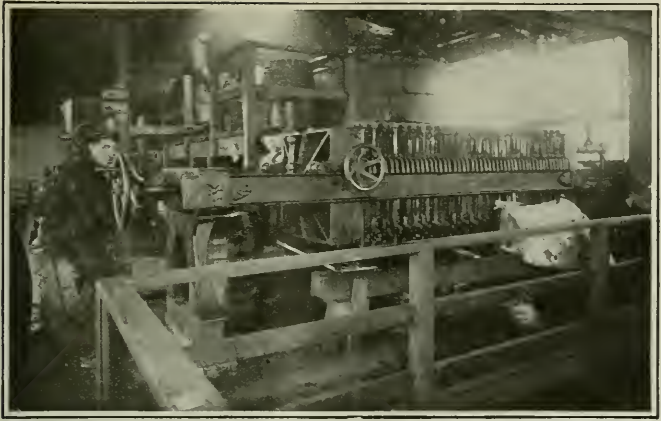
Caustic Fusion is performed chiefly with sulfo acids, occasionally with chloro derivatives. The hydroxyl group, OH, replaces chlorine or the sulfo group. Thus benzene-sulfonic acid, on fusion with caustic soda, yields phenol, or carbolic acid, C_6H_5OH.

Alkylation.—This term is usually applied to the replacement of hydrogen in the hydroxyl or amido groups of aromatic compounds, by the radicals methyl, CH_3, or ethyl, C_2H_5, present in wood alcohol or in grain alcohol. The alcohols or methyl or ethyl chloride are used along with hydrochloric acid, and the operation is effected at elevated temperatures, under pressure. As an example, aniline, $C_6H_5NH_2$, can be transformed into methyl-aniline, $C_6H_5NHCH_3$, or dimethyl-aniline, $C_6H_5N(CH_3)_2$.

Condensation.—This term refers to a large class of operations, in which two molecules of the same substance, or of different substances, unite to form a new compound, with elimination of water, ammonia, or hydrochloric acid. Sulfuric acid, in considerable excess, is the usual condensing agent. The chlorides of aluminum, antimony, phosphorus, sulfur and zinc are occasionally employed for the purpose. The manufacture of the so-called ketone group of colors is a good illustration of condensation on a wholesale scale. Use is made here of the compound known as tetra-methyl-diamido.benzo-phenone, termed Michler's ketone, after the inventor. By condensation with twenty-four different coal-tar intermediates, this yields the same number of widely used artificial colors. Thus from the condensation of the ketone with benzoic acid chrome green is obtained; the reaction with dimethyl-aniline gives methyl-violet, etc.

Diazotizing and Coupling.—The formation of diazo compounds is one of the most important in the whole range of color manufacture. Any primary amine, such as aniline, yields on treatment with nitrous acid, HNO_2, the corresponding diazo derivative. Thus aniline, in the presence of hydrochloric acid, changes into diazo-benzene chloride, $C_6H_5N{:}N\text{-}Cl$. The reaction is simple and quantitative, the most easily controlled of all the reactions of color manufacture. An essential condition of success is to maintain the temperature below 4° C., preferably at zero. The diazo compounds, as a rule, can exist only in a cold solution. In this form they react most readily with a great variety of aromatic substances. The term coupling is applied to this reaction. Thus the diazo-benzene chloride mentioned above, upon gently warming its solution with aniline, yields amido-azo-benzene chloride, $C_6H_5N{:}N\text{-}C_6H_4NH_2\ HCl$, the well known dye aniline yellow. With m-phenylene-diamine, the same compound yields another famous dye, chrysoidine.

Carboxylation.—The introduction of the acid carboxyl group, COOH, into the molecules of phenol and its homologues is effected by the joint action of caustic soda and carbon dioxide. Thus phenol, C_6H_5OH, is



LARGE FILTER PRESS IN OPERATION.

(Courtesy the Scientific American.)

easily transformed into salicylic acid, $C_6H_4.OH.-COOH$.

Liming.—Occasionally the products of sulfonation or chlorination are treated with lime, in order to accomplish the separation of several closely allied compounds by means of the differing solubilities of their calcium salts.

Fusion with Sulfur and Sulfides.—An important class of dyestuffs, the so-called sulfur colors, is prepared by the fusion of various coal-tar intermediates with either sulfur, alkaline, sulfides, or mixtures of the two.

The above constitute all the major chemical operations in use by the manufacturer of artificial colors. We must bear in mind, however, that the possibilities of the coal-tar compounds are from the theoretical standpoint literally numberless. For every synthetic dye which has actually conquered its position in the commercial world, somewhere between a hundred and a thousand tinctorial compounds have been created by the coal-tar chemists, tried, and found wanting. Few of these are chronicled with any fullness of detail.

Mechanical Operations of Color Manufacture.

The visitor to a color factory gazes upon a bewildering maze of closed and open containers, pipes and stills and presses. When subjected to strict classification, however, there are but a few general types.

The operations outlined above are carried out under varying conditions of temperature and pressure. In most cases constant agitation of the contents of a vessel is necessary. This is effected by a series of blades attached to a central axis. Heat is usually communicated by circulation of steam through coils of pipe contained in the vessels in which reactions are under way. Frequently, however, these are jacketed with an outer wall so that steam surrounds the entire bottom and sides.

It is often the case that volatile products or noxious fumes are emitted. Here the vessels are tightly covered, with suitable vents. Occasionally condensers are attached, so that volatile liquids are not lost, but flow back constantly into the chamber where the reaction is taking place. In numerous instances the reaction must go on under high pressure. The heavily constructed vessels provided for this purpose, with agitating mechanisms and steam jackets, are termed autoclaves. Necessary adjuncts are thermometers, pressure gages and safety valves.

Of all the mechanical operations involved, that of filtration is the one which appeals most to the eye. The batteries of modern filter presses, highly perfected in every detail, render it possible to separate precipitates in an incredibly short time, and to wash them free from the last trace of the liquors in which they have been produced. The swiftly whirling centrifugal, of such vast convenience to the sugar manufacturer, also comes frequently into play. Vast drying chambers are, however, in constant requisition to remove every vestige of moisture from finished dyestuffs, before they are packed for shipment.

The Evolution of H-acid.

To illustrate in concrete form the workings of a coal-tar color factory, the sequence of operations in the manufacture of a single intermediate may be outlined. Choice will be made of one with a somewhat formidable chemical name—1.8-amido-naphthol-3.6-disulfonic acid. In commerce and in the color factory it is ordinarily termed H-acid.

The starting point is naphthalene, $C_{10}H_8$, secured, in a crude form, from the carbolic oil fraction of coal-tar distillation by allowing the latter to stand for a few days at as low a temperature as possible. The impure crystals are fused and allowed to recrystallize slowly in large vats. This product is washed with hot caustic soda solution to remove phenols, with strong sulfuric acid to remove bases, and finally with very dilute caustic soda. It is then submitted to heavy hydraulic pressure in bags, or is whizzed in a centrifugal and is ready for most uses. If desired in very pure form it is either distilled again or sublimed.

ONE OF THE STEPS IN THE MANUFACTURE OF H-ACID.

(Courtesy the Scientific American.)

Five successive main steps are required to transform this purified naphthalene into the desired acid.

1. Naphthalene is heated for several hours with concentrated sulfuric acid at 180° C. The product is dissolved in water, freed by filtration from a little dinaphthyl-sulfone formed at the same time, and by addition of common salt, precipitated in the form of sodium salt of b-naphthalene-sulfonic acid, $C_{10}H_7SO_3H$.

2. This is next submitted for a short time to the action of concentrated sulfuric acid at 160°. The main product is naphthalene-2.7-disulfonic acid. A certain amount of the isomeric 2.6-acid is formed at the same time. By liming the two are separated; the calcium salt of the latter is insoluble in water, while that of the former is easy soluble. After filtration the calcium salt is decomposed by sulfuric acid, and naphthalene-2.7-disulfonic acid, $C_{10}H_6(SO_3H)_2$.

3. This acid next undergoes nitration. The product is 1.8-dinitro-naphthalene-3.6-disulfonic acid, $C_{10}H_4(NO_2)_2(SO_3H)_2$.

4. This in turn undergoes reduction yielding 1.8-diamido - naphthalene - 3.6 - disulfonic acid, $C_{10}H_4(NH_2)_2(SO_3H)_2$.

5. Upon treatment with dilute sulfuric acid at 120 one of the amido groups, NH_2, in the last-mentioned acid is replaced by the hydroxyl group. The resultant product, $C_{10}H_4.OH.NH_2.(SO_3H)_2$, is the desired intermediate, H-acid.

The numerals in the above formulae serve to indicate the relative positions in the naphthalene molecule of the substituting groups and thus to distinguish between the various isomers. Theoretically there are 210 possible amido-naphthol-disulfonic acids. A relatively small number of these are actually known.

The pathway from naphthalene to H-acid is evidently tedious and complicated. The coal-tar crude costs today 9 cents per pound; the H-acid is quoted at $2.50.

Colors Evolved from H-acid.

When the color manufacturer, however, once has this helpful intermediate in his possession the way is open for the easy production of a large variety of staple dyes by the successive steps of diazotizing and coupling, as described above. With the help of aniline and p-nitraniline, or sulfanilic acid and a-naphthylamine, or aniline, benzidine and m-phenylene-diamine he can make excellent blacks, the rapid production of which, on a large scale in American works, has been of pronounced assistance in lessening the discomforts of the color shortage during the past year. Using other similar combinations with intermediates of simpler manufacture, and the all-potent diazo reaction, we can produce a great variety of standard blues, violets, greens, mauves, olives, bronzes, blacks and blue-blacks, each possessing its own individuality, each of specific applicability to some of the many phases of the dyer's art. All are dependent for their production upon H-acid and the sequence of chemical and mechanical operations outlined above, as well as upon the series of operations involved in the preparation of two or three less complicated accessory intermediates required at the final step in the evolution of each separate color.

In reviewing this complex of chemical and mechanical activity, and in considering the highly specialized human intelligence needed to control and coordinate the multiple factors, need we wonder at the confidence of those directing the great color works of Germany in asserting that a comprehensive American coal-tar dyestuff industry could never be created? And can we refuse an ample measure of patriotic admiration and generous cooperation to the plucky American chemists who are, today, actually creating that selfsame industry? T. H. Norton.

FINAL STEPS IN THE EVOLUTION OF AN ARTIFICIAL DYE

RECENT STUDIES IN COLOR CHEMISTRY

The most important articles in recent foreign journals bearing on the problems of the color chemist are here grouped together.

Contributions to the Chemistry of Caramel. Part I, Caramelan.

By M. Cunningham and C. Doree, Jour. Chem. Soc., 1917, *111*, 589.

Although caramel has been used industrially, notably for the coloring of foods, very little is known of its composition. In company with other coloring matters derived by simple processes from natural products, it is assumed that it is harmless. This is not necessarily true, however, and any addition to our knowledge of the chemistry of caramel such as the study by M. Cunningham and C. Doree is of especial interest to manufacturers and consumers of food products.

When sucrose is heated to 180-190° three products are formed, caramelan, $C_{12}H_{18}O_9$, caramelen, $C_{36}H_{48}O_{24}$, and caramelin, $C_{24}H_{26}O_{13}$, by processes of dehydration and polymerisation. The first mentioned is the subject of the paper.

The authors considered that a study of the process of formation of caramel in the simpler sugars, apart from its specific interest, might have a bearing on the question of the constitution of cellulose in its relationship to the carbohydrates and especially on the connected problem of the formation of humus, peat and coal. Thus sucrose being the precursor of cellulose in plants, the sequence would become sucrose or cellulose, caramelan, humic acid, humin, and finally carbonization to peat or coal.

The constitutional formula of the cellulose unit group in its relation to this formula for sucrose and possible formulae for caramelan is discussed. A resumé of previous work on caramel compounds, the methods of preparation of the pure compounds, their reactions with metallic salts and the effect of heating to different temperatures upon the character of the solid and volatile products are taken up. This is followed by extensive experimental work on the preparation of caramelan and its esters with acetic, benzoic and nitric acids. The aldehydic or ketonic character of caramelan was shown by its compounds with phenylhydrazin in the presence of acetic and sulfuric acids and also its reaction with semi-carbazide. The action of acids, such as 3% sulfuric, 12% hydrochloric and 40% hydrochloric was used to determine whether hydrolysis produced simpler carbohydrates from caramelan. Careful tests of the liquid and solid products were made and throughout the work the formula of each substance obtained was determined by ultimate analysis. Carmelan was subjected to acetolysis and to the action of oxidizing agents such as nitric acid and bromine water. Conclusions reached may be summarized as follows:

Sucrose, on heating to 170°-180° loses two molecules of water, forming caramelan, $C_{12}H_{18}O_9$ or $C_{24}H_{36}O_{18}$, a tetratomic alcohol, m.p. 136°, characterized by the formation of a tetra-acetate, m.p. 107°, a tetrabenzoate, m.p. 105°, and a tetranitrate which is explosive. The second molecular formula is probably correct.

Compounds of caramelan with phenylhydrazin and semicarbazide indicate the existence of one CO or CHO group for each C_{24} unit, formed with extensive dehydration.

Concentrated non-oxidizing acids cause dehydration to caramelin, while weaker solutions hydrolyze and dehydrate, producing dextrose, methylfurfuraldehyde and humic acid.

On oxidation caramelan yields more complex substances, one carbon atom per each C_{24} unit being removed. Acetaldehyde was recognized among the products. Nitric acid forms characteristic nitro-acids.

Caramelan seems to be the first step in the process of anhydride formation and condensation which leads from simple sugars to such complex substances as cellulose, caramelin and humus.

Cochineal.

C. F. Muttelet, head chemist in the central laboratory for the control of adulteration in foodstuffs, France, reviews briefly in Annales des Falsifications for May-June, No. 103, page 228, the reactions and tests applied by that laboratory for detecting the presence of cochineal carmine or ammoniacal cochineal in foods. The long-used test for cochineal, which depends on the emerald green color given when a small amount of uranium acetate is added to the amyl alcohol extract of an acidified solution of the sample, shows a like color when carmine is present and a violet amethystine shade with ammoniacal cochineal. When such colors are yielded by this test of a food, presence of cochineal in some form may be suspected and further confirmed.

The color is first extracted from the foodstuff by amyl alcohol, the extract evaporated on the steam bath, the residue taken up in water and filtered.

Ammoniacal Cochineal.

In a state of powder ammoniacal cochineal is of a violet-gray color, as a solid it is violet-brown and both dissolve in water with a purplish violet shade. The filtered solution, evaporated to dryness on the water bath, leaves a reddish violet residue which dissolves in concentrated sulfuric acid when a brownish orange color, becoming successively yellow then brown and violet when water is added. The solution becomes violet on addition of ammonia, is but little altered by hydrochloric acid, is completely extracted from acid solution by amyl alcohol giving this solvent a cherry red color and the amyl extract yields, as stated before, a violet-amethyst color with acetate of uranium.

Cochineal Carmine.

The carmine-red solution is filtered then evaporated to dryness on the water-bath, which gives a ponceau-red residue dissolving in concentrated sulfuric acid with a cherry-red shade which the addition of water changes from orange yellow to orange. Ammonia colors the solution reddish-violet, hydrochloric acid causes an orange tint; the amyl alcohol extract of the acid solution is orange red and gives an emerald green color with uranium acetate.

Some ammoniacal cochineals partly revert to cochineal carmine. This follows from the method of manufacture which consists in treating cochineal carmine under determined conditions by ammonia. The carminic acid is transformed into carmin-amid which gives to ammoniacal cochineal its peculiar properties. It may be in some instances that this change is incomplete in which case the product reverts again to carmine. These two coloring matters, when present together in a strongly colored substance, may be characterized in the following manner:

The amyl alcohol extract of the color is added to an excess of powdered carbonate of lime, and after some hours of contact the whole is thrown on a filter. The amyl alcohol passes through practically uncolored, the precipitate is washed on the filter with a little 95% alcohol, which removes only traces of the color, and then cold water is added. This becomes strongly colored a red shade while the residue on the filter is tinted violet gray.

The red aqueous solution is acidified with hydrochloric acid and extracted with amyl alcohol, which takes up all the color with a raspberry red shade and gives with uranium acetate the characteristic amethyst-violet shade due to ammoniacal cochineal.

The calcium lake remaining insoluble on the filter is decomposed by dilute hydrochloric acid, forming an orange liquid which yields all its color to amyl alcohol, the orange-red amyl extract giving the emerald-green color with uranium acetate.

In addition to the reaction with uranium acetate there is one other of equal interest, notably the effect of fixed alkalies, an effect of special importance when ammoniacal cochineal is considered as an amid of carminic acid. Theoretically, the fixed alkali changes the ammoniacal cochineal back again into the original carmine, setting ammonia free. Thus the ammoniacal cochineal can be characterized by two color reactions, the amethyst-violet shade given directly and the emerald-green shown indirectly after treatment with fixed alkali, which transforms it into carminic acid.

The test is as follows: An aqueous solution of ammoniacal cochineal is added to its own volume of caustic soda, 30° Bé. The violet tinted mixture is heated to gentle ebullition under a reflux condenser. Ammonia is disengaged and the liquid little by little becomes of a purple shade. After 30 to 40 minutes heating the transformation is complete, and the cooled liquid is made acid with hydrochloric acid, which changes its color to the coppery-orange of acid solutions of cochineal carmine. Extracted with amyl alcohol the latter becomes orange red and gives the emerald green color with uranium acetate.

In order to be assured that all of the ammoniacal cochineal has been transformed into carmine the amyl alcohol extract may be treated with powdered carbonate of lime, as previously described. All of the color should be rendered insoluble. The gray-violet precipitate, after being washed with 95% alcohol should yield no color to cold water if it contains no ammoniacal cochineal. Decomposed with hydrochloric acid, however, it gives the reactions of the carmine lake of cochineal.

It is of interest to note that carmine, which as a food coloring is essentially an aluminum lake of cochineal, can be decomposed by concentrated hydrochloric acid and carmine acid extracted by amyl alcohol in much greater abundance than is obtained by the foregoing test so that with uranium acetate very strong color reactions are obtained.

Fastness of Dyestuffs—Standards and Processes.

Established by the "Echtheitskommission," Second Report to the Ver. deutsch. Chem., by P. Heermann, Mitt. k. Materialprüf., 1916, *34*, 153; J. S. C. I., 1917, *36*, 590.

Certain standards prescribed in the first report (J. S. C. I., 1914, 248), have been modified and replaced by the following:

1. *Fastness to light* (1a) Fastness of dyed cotton. The sample is exposed together with the dyed standard in a box suspended in the open under glass, one half of the object being covered by paper or cardboard. At the Materialsprüfungsamt two exposures are always made, one under glass and one in the open, subject to all atmospheric influences. Dressed goods are faster to light than undressed. The type standards are: I, 5% Chicago Blue 6B (424) dyed at the boil with two additions of Glaubers salt. II, 0.8% Methylene Blue BG (659) dyed cold to warm with 2% of acetic acid on a 3% tannin and 1.5% antimony salt mordant. III, 1% Indoin Blue on cotton mordanted as in II. IV, 20% Kryogen Violet with 1.5 times its weight of crystallized sodium sulfide, dyed at the boil with the addition of soda-ash and salt. V, 2.5% Benso Light Red 8 BL, dyed as in I. VI, 10% Hydron Blue G 20% G 20% paste (748) dyed at 60° C. with NaOH and 5% hydrosulfite. VII, 8% Sulfur Black T ext., (720) dyed as in IV. VIII, 25% Indanthrene Blue G C paste, dyed with 6.25% hydrosulfite and NaOH.

(1b) *Fastness of dyed wool.* Tests same as for cotton, exposure of piece goods both under glass and in open. Type standards are: I, 3% Indigotin Ia, powd. (877) dyed at the boil with 10% Glaubers salt and tartar. II, 1.5% Ponceau RR (82) dyed same way. III, 2.75% Amaranth (168). IV, 4.5% Azo Acid Red B (64). V, 5% Acid Violet 4RN (Bad) with Glaubers salt and acetic, from 40 C to boil, finished at boil with sulfuric. VI, 2.5% Diamine Fast Red F (343) after-chromed. VII, 4% Anthraquinone Green GXN (864) dyed as in V. VIII, Indigo (874) dyed to a shade equivalent to 2.4% Sulfocyanin GR ext. (257) or 7% Naphthol Green B (4) dyed with 10% Glaubers salt and tartar, beginning at 50° and finishing at boil for 1 hour.

2. *Fastness to kier-boiling of dyed cotton.* Two tests are made. (A) 5 grams of the dyed sample are intermingled with equal wt. bleached cotton and mixture boiled with ten times its wt. of liquor to which has been added 10% caustic soda, 40°Bé., (sp. gr. 1.357) calc. on wt. of material, for 6 hours at constant vol. (B) Treatment is repeated as under A with addition of 1% "Ludigol" on wt. of material. Standards:—I. The shade is distinctly paler after both treatments and the white cotton somewhat stained. III. The shade is appreciably paler after both treatments but the white cotton shows no more than a trace of stain. In the same class are included cases where the shade becomes paler, when treated as under A and the white cotton is stained but when treated by the B process the white cotton is not stained. V. The dyed cotton under both treatments remains entirely unchanged and the white cotton shows no more than the slightest trace of a stain. Types:—I. Normal Paranitraniline Red dyeing, boiled with soap after development. III. Indigo dyeing to the same depth as 3% Diamine Fast Blue FFB, or 10% Indanthrene Yellow G paste (849) boiled with soap after dyeing. V. Normal Turkey Red (Old Red) dyeing.

3. *Fastness to Decatising of Dyed Wool.* Three tests are applied. (A) The sample is rolled up with the usual material on a decatising cylinder in six layers uniformly and firmly, or in the case of small samples a layer of decatising cloth is wound on first, three further layers are wound on and the whole tied up. The material is steamed for ten minutes counting from the time when the steam begins to issue through the cloth, let stand for five minutes and unwound. (B) The prepared cylinder is steamed for five minutes in a closed vessel under one atmosphere pressure (C) It is steamed for ten minutes under 2½ atmospheres pressure The standards are, I Under treatment (A) a fairly strong change in shade. II. Under treatment (A) no change in shade. III. Under treatment (B) fairly strong change in shade. IV. No change. V. Under treatment (C) no change. Types: I. 2% Thioflavine T (642) dyed at 50 C for ¾ hour. II. 2% Sulfocyanine GR ext. (257). III. 2% Sulfocyanine IV. 2% Croceine AZ (255). V 9% Naphthol Black 6B (269) with 10% tartar, beginning at 40 C and finishing at the boil for one hour.

Sensitizers.

According to Hans Waago in the Danish "Amator-Fotografen," January, 1917, issue, the use of a sensitizer such as Erythrosine for carbon tissue or gum paper enables printing to be carried out in poor daylight or strong artificial light in which bichromated tissue, because of insensitiveness to any but blue-violet rays, will not print. Dr. A. A. Meisling, another Danish scientist, has used Auramine and other dyes also, but has worked most with Erythrosine, results with paper sensitized with aniline colors having been shown as early as 1908 before the Royal Danish Scientific Society.

Water solutions of the dye at dilutions of 1:1000 up to 1:10000 are recommended for detailed and rich prints, the greater the concentration of the dyestuff the more the effect being confined to the surface of the coating. Photometer tests show greater sensitiveness with damp than with dry paper. Erythrosine-sensitized papers are not inferior to bichromated ones in sensitiveness and in poor daylight their green sensitiveness makes them faster than the blue-bichromated papers. When dry and protected from light they will keep in good condition for six months or longer Being less sensitive when dry they should be soaked in water for two or three minutes before use.

To prepare the paper the inventor uses ready-prepared Hochheimer pigment paper which is placed face down in a 1:10000 solution of the dye, bubbles are removed with a brush or wad of cotton wool, and the paper is then turned over and the solution poured over the face. Three minutes is required for sensitizing a paper for immediate use and four minutes when the paper is to be kept. After removing from the sensitizing bath allow to drain for a short time, then dry in well ventilated dark room.

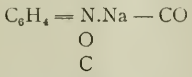
Intravital Staining with Acid Dyes.

W. Schulemann, in the Bichemische Zeitschrift, 1917, *80*, pages 1 to 142, also in Kolloid Zeitschrift, 1917, *20*, page 113 *et seq* discusses the theoretical considerations relative to intravital staining with acid dyes and its significance for anatomy, physiology, pathology and pharmacology. The size of the dye particles affects their ultimate distribution as well as the rate of coloring of an organism. There appears to be no relation between the chemical constitution of a dye and its capacity for intravital staining, the side-chain theory of Ehrlich not being sufficient to explain the action of dyes injected into the living organism. There is, however, a close relation between the rate of diffusion in gelatin gels and intravital staining.

The author considers methods of assimilation and storage of dyes by cells, the relation between amoeboid movement, phagocytic action and capacity for staining, influence of surface, tension and other factors, nature of "granula" and "metachromatism," or differences in colors of dyes in different cells due to amount and character of electrolytes.

Constitution of the Blue Isatin Salts.

The various forms of isomerism in the blue isatin salts and a study of these phenomena by means of the stability of the N and C salts toward water have been described and discussed by M. Claasz in the Berichte, 1917, *50*, page 511. The "internal salt" formula containing Claasz's indigo chromophore



$$\begin{array}{c} C_6H_4 = N.Na - CO \\ O \\ C \end{array}$$

is considered the most plausible.

Color Theories.

Hugo Kauffmann, in an article in the Berichte (1917, *50*, 630) warns against an exaggerated idea of the importance of the degree of unsaturation of a chromophore in connection with color theories. For instance, ethylene and aniline are colorless, while more saturated stilene derivatives, or 1.3.5. trinitrobenzene, are colored yellow or red. The degree of saturation of an ethylene linking is raised by the proximity of a phenyl, carboxyl, carb-ethoxyl or cyano group, but in three cases the color is quite opposite. Unsaturation may confer chromophoric properties on atomic groups but in no sense determines the degree of chromophoric activity.

In a previous article (Ber. 1917, *50*, 515), Kauffmann investigated chromophores with auxochromic functions by a study of the color and fluorescence of compounds of the two types $N.Me_2.C_6H_4.Chr$ and $Chr.C_6H_4.Chr$, and reasons that the brilliant fluorescence shown by these compounds is the result of auxochrome activity of the chromophores in accordance with the rule that a second auxochrome in para position to another yields strongly fluorescent di-derivatives. A tabulation of data on solid compounds is given.

Apparatus for the Color Laboratory.

A convenient form of autoclave or bomb is described by G. W. Morey in the Journal of the Washington Academy of Sciences, (1917, *7*, 205). It is made from 8.7 centimeter pipe, closed by welding on an iron bottom, the upper end also having a cover with an outer rim that presses against an inner shoulder on the outer shell. The outer shell is made of ten centimeter pipe. Closure is made by compression of a gold wire washer and is effected by a bolt threaded through a cross bar fixed to the lower end of the outer shell.

This apparatus may be used with aqueous solutions up to 300°C., and is superior in ease of construction, of manipulation and certainty of closure.

Methyl Red As An Indicator.

In a study of the merits of Methyl Red as an indicator, F. Lehmann and G. Wolff, (Arch. Pharm., 1917, *255*, 113), report that this color is more sensitive to both hydroxyl and hydrogen ions than is Methyl Orange. Oxalic and picric acids can be titrated readily, also alkali borates and cyanides. Sulfites, sulfides and carbonates do not yield sharp end points. This indicator gives standard solutions of practically the same normality as phenol-phthalein, two drops of a one-tenth per cent. solution in one hundred cubic centimeters of a liquid leading to the best results.

Aniline from Ammonia and Benzene.

The formation of aniline from ammonia reacting with benzene at high temperatures in the presence of contact catalysts is the subject of an article in the Berichte, 1917, *50*, 541, by J. P. Wibaut. The author has obtained but a low yield of aniline when benzene and ammonia vapors are passed at 550° to 560°C. through iron tubes containing reduced iron, nickel or copper. The best results followed the use of a stream of ammonia vapor bubbling through liquid benzene at 75°C.

Bixin.

A further study of Bixin, the essential coloring principle of Annatto, by A. Heiduschka and A. Panzer, (Berichte, 1917, *50*, 546) emphasizes the importance of obtaining plant colors in a pure condition. Much depends on the method of isolation and purification, the most reliable specimens in the case of bixin being purified by acetone, then crystalized from ethyl acetate. Molecular weight determinations and analyses of the compound itself as well as its methoxyl derivatives confirm the formula $C_{25}H_{30}O_4$ previously obtained by Herzig and Faltis (Annalen, 1915, *1*, 572.)

An Absolute System of Color Classification.

W. Ostwald, in the Zeitschrift für physicalische Chemie, 1917, *92*, 222, explains his system of classification of colors, the equation involving three terms, $R + W + S = 1$, where R is pure color, W represents white and S black. Colors are tabulated by this system in relation to frequency of vibration, the pure color factor R being determined in terms of the frequency of light in the visible spectrum.

Artificial Color in Alimentary Pastes.

M. P. Balavoine, in the Schweizerische Apotheker Zeitung, 1917, page 141, suggests the following method for determining artificial color in macaroni and other pastes: Twenty grams of the pulverized paste are extracted with 40 cc of ether; the residue dried and again ground is treated with 40 cc of fifty per cent. alcohol. The alcohol is removed by decantation, is filtered or centrifuged, and the extraction is repeated two or three times if necessary. In a 250 cc Erlenmeyer flask 100 cc of water are brought to a boil and the alcoholic extract is added drop by drop, with care, as the liquid foams strongly. This concluded, 5 cc of 10% sulfuric acid are added and the liquid kept at a gentle boil for a quarter of an hour. It may then be used as a dye-bath for coloring a piece of wool

New Coloring Agents for Microscopy, Derived from Methylene Blue.

Messrs. L. Tribondeau and J. Dubreuil have elaborated the method of preparation of Methylene Azure and Methylene Violet. (See abstract in Journ. de Pharm, et de Chim., 1917, *16*, No. 2, page 53) from Methylene Blue.

Egg Color.

Under the title "The Coloring Matter of Egg Yellow, Ovochromin," N. A. Barbieri in Comptes rendus, 1912, *154*, 1726, outlines the method for separation and identification of this color, the recognition of which is of so much importance to food analysts.

Egg yolk is extracted first with carbon disulfide, then with 95% alcohol, until the solvents are no longer colored. They are then separated, the alcoholic portion filtered, evaporated to a paste and redissolved in chloroform. The liquid forms three layers, a watery stratum above, solid white in the middle and chloroform below. Only the water layer contains the egg color, which may be precipitated by acetone and purified by repeated solution in water and precipitation with acetone or dialyzed in aqueous solution. Upon evaporation of the aqueous solution ovochromin appears as a yellow-odorless powder, strongly deliquescent, soluble in an equal weight of water, insoluble in alcohol, ether, chloroform and soluble in fats. It carbonizes at 270° without melting, is weakly acid, gives no biuret reaction and has no albumin or pepton characteristics. It may be declorized by hydrogen peroxide. The ultimate composition is C-42.60% ; H-6.70%, N-8.08% ; S-1.60% ; 0-40.78% Fe- 0.235%. It showed no toxic properties.

Color Tests for Palm Oil.

According to A. H. Gill (J. Ind. Eng. Chem., 1917, *9*, 136), the data obtained on the Crampton-Simons test for palm oil shows conclusively that it is no longer available for testing oleomargarine. The test is unreliable, because of the difficulty in its interpretation, and still more because carotin rather than palm oil is the real cause of the reaction and the test therefore may be obtained with butter, oleo oil, or sesame oil, ingredients ordinarily found in oleomargarine and which cannot be washed out. Further study is in progress.

Color and Chemical Constitution.

Dr. James Moir, in a paper read before the Royal Society of South Africa, describes the color changes produced by substitution in some fifty derivatives of phenolphthalein and fluorescein. The most striking novelty in the paper is the discovery that when these substances are dissolved in concentrated sulfuric acid they give a coloration which is five times as intense as in alkali, and is produced by a band of lower wavelength, the frequency being half as fast again in sulfuric acid after allowing for a constant load due to combination of sulfuric acid with the oxygen of the dye. As, however, fluorescein in alkali and phenolphthalein in sulfuric acid give identical absorption bands, it is suggested that there is in each case a linking up of the phenolic rings.

Cold Facts on a Warm Subject

The Bureau of Mines, Department of the Interior, recently asked the advice of a number of prominent fuel engineers throughout the country as to the best way to conserve in the use of coal during the period of the war. Martin A. Rooney, of Detroit, Mich., had the following to say:

"In every train load of coal laboriously hauled from the mines to our coal bins *one* carload out of *every five* is going *nowhere* and worse. In a train of forty cars the last eight are dead load that might better have been left in the bowels of the earth.

"Every fifth shovel full of coal that the average fireman throws into his furnace serves no more useful purpose than to decorate the ***atmosphere*** with a long black stream of ***precious*** soot. These are not meaningless statistics nor a 'Goblin' story, but ***cold*** *facts* on a warm subject. At best, ***one-fifth of all our*** *coal is wasted.*

"And it is shamelessly and needlessly wasted. Instruments and machinery for getting out all of the heat there is in it are not nearly so complicated nor expensive as the cash register which you use to keep tab on your cash receipts or the truck which you operate to clip a few cents off of your delivery costs.

"Carbon dioxide *temperature and draft* are easier subjects to comprehend than bank discount or freight rates.

"The moral is, Mr. Coal Dealer, get busy and learn what they are and how to use them. The time is coming when the Government is going to limit the amount of our coal that is dumped down your chute and in the name of fairness, when we must deny fuel to some manufacturer, let it be to him who can not show that he is going to use it efficiently. In the name of fairness to the miner who digs it, in fairness to the heavily burdened railroad which transports it, in fairness to a number of our people whose very existence and whose future happiness depend absolutely on the use we make of this most precious of our resources, let us *make efficiency the criterion to judge by* when we come to determine which shall survive.

"And in fairness to the manufacturer who is patriotically operating his properties at nearly to the breaking speed and who is giving up a large part of his profits for the general good let the Government *show him how to conserve* this most important of his raw materials.

"Let us send in to our furnace and boiler room men who can show our engineers and firemen how to burn their fuel with the least waste, as we have sent them among our fields and orchards to show the farmer how to increase the productivity of his soil."

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By Carleton Ellis and A. A. Wells.*

PART XI

Drying of Linseed Oil.

In studying the phenomena of drying linseed oil *Genthe* (Z. angew. Chem. 1906, 2090) made use of the ultra violet light. Uviol lamps made by Schott and Genossen in Jena were employed. The oil was exposed on filter paper to an atmosphere of oxygen in a quartz flask shown in *Fig 1*. A series of these flasks were supported on a special stand, shown in *Fig. 2*, and exposed to the Uviol lamp, during which exposure the absorption of oxygen was measured. Caustic potash was placed in the bottom of the vessel to absorb volatile acid products. No formation of ozone was noted, and in *Fig. 3* curves of oxygen absorption are shown (experiments 79, 80 and 81). During the first two hours the absorption of oxygen was slight. In the third hour the absorption became very rapid, gradually diminishing in rate during subsequent hours of insolation. In *Fig. 4*, curves 73, 74 and 75 are for exposures of linseed oil under same conditions as above except the caustic potash was omitted. Curve 76 is for linseed oil varnish.

To determine whether or not the volatile products of the reaction were capable of exerting a catalytic action, apparatus shown in *Fig. 5* was used. A tube of Uviol glass was filled with fragments of pumice which had been impregnated (in vacuo) with linseed oil. This tube was placed 3 cm from an Uviol lamp. A stream of oxygen was passed first through the tube and then into a Dewar flask maintained at a temperature of −20° C. After 48 hours several grams of a strongly acid liquid had condensed. Some of this liquid was added to linseed oil and the rate of drying was observed. No difference over pure oil was noted.

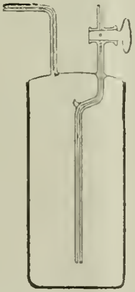


Fig. 1.—Quartz Flask Employed by Genthe for Drying Linseed Oil.

On an average, the oxygen absorption at room temperature was 23 per cent. in the dark and 25.8 per cent. in the ultra violet light. At 95° C. the absorption was 26.5 per cent. and 34.7 per cent., respectively . Beside the main reaction bringing about absorption of oxygen, there is a slow combustion of the organic substance. In light and at higher temperatures this destructive oxidation is considerably augmented. Oxidation is accompanied by polymerization. The weight of the volatile reaction products amounts to 15 per cent.

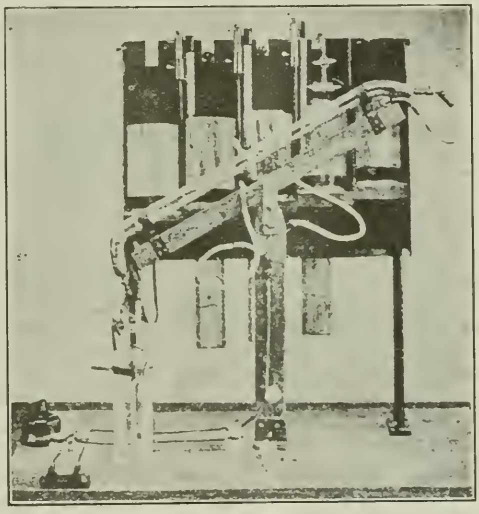

Fig. 2.—Series of Flasks Arranged for Exposure to Ultra Violet Rays.

Other Fatty Oils.

The treatment of vegetable oils by ultra violet light to yield thickened products is described in some detail by *Ellis* (U. S. patents 1,179,414 and 1,180,025, April 18, 1916). Various oils such as linseed, Chinese wood, corn, cottonseed, castor, peanut, fish and whale oils and also resin oils are thickened by exposure to ultra violet radiation. From corn or cottonseed oils, products of the viscosity of castor oil may be prepared and used as castor oil substitutes. An oil which has been exposed in this manner may be subsequently vulcanized with sulphur, when it will be found that less sulphur is required than would be needed to give the original oil the same degree of solidity or elasticity The light-treated oil may be mixed with rubber and vulcanized. In exposing the oil, the fumes which are formed by the action of the light or heat should be removed. This may be done by passing a current of air or other gas over the surface of the oil. The fumes interfere with the free radiation of the ultra violet light and reduce its effectiveness. The oil may be treated in thin layers flowing past the source of light and an inert gas may be caused to flow through the apparatus to exclude oxygen and sweep out the fumes which may be formed. Carbon dioxide is suited for this purpose. From linseed oil a solid product is formed and Chinese wood oil is very quickly solidified to a transparent rubbery material. These light-treated oils may be used in lubricants, varnishes, printing ink and linoleum as well as rubber substitutes.

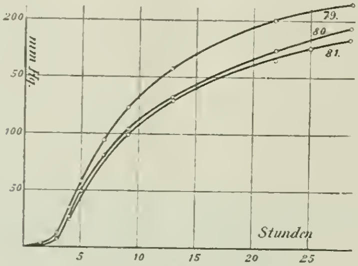

Fig. 3.

Bleaching of Rosin.

A very simple method of bleaching rosin by ultra violet rays is described by *Minor* (U. S. patent 939,733, November 9, 1909). *Fig. 6* shows the apparatus used for the purpose. This consists of a receptacle containing the rosin in a molten state. The receptacle rests on a gas oven used to maintain the requisite temperature. In the walls are placed ultra violet lamps having bulls-eyes through which the rays pass into the rosin. Minor states that the color of the rosin is lightened by this treatment and that the bleaching effect may be varied by longer or shorter exposure to the ultra violet rays.

Polymerizing Action.

A substitute for drying oils as a medium for paints, varnishes and impregnating agents for fabrics, wood, etc., is proposed by *Rohm* (J. S. C. I., 1917, 296 German patent 295,340, June 5, 1915) which consists of a solution of polymerized acrylic acid ester, in acetone, lower fatty esters, or other solvents. The acrylic esters may be prepared from allyl alcohol, glycerin, lactic acid, etc. When exposed to sunlight or artificial ultra violet light, they are transformed into a colorless, transparent, very elastic (not gelatinous) tough mass, which is soluble in the solvents for oils. Alternatively the ester may be mixed with a solvent, and the mixture polymerized. The polymerized ester dries rapidly, resists many chemical agents, and is not readily affected by exposure to weather.

Sterilizing Butter.

A method of improving the keeping qualities of butter has been based upon the sterilizing action of ultra violet rays upon the water used for washing the butter in the dairy. It has been pointed out by *Dornic* and *Daire* (Comptes Rend., 1909, 149, 355) that it avails little to prepare butter from sterilized cream if the water used for washing it contains micro-organisms that tend to produce rancidity. The apparatus employed by Dornic and Daire consists of a tank lined with glass, and provided with glass partitions over which the water passes, and receives the rays from two quartz electric lamps, which are inserted through holes in the cover of the tank. About 3,000 litres of water can thus be rendered practically sterile in a day, the number of bacteria being reduced by the treatment of an insignificant quantity. The cream, or butter itself, might be rendered sterile by this process, but an unpleasant flavor produced by the action of the ozone formed by the lamps prevents the method being successfully employed in practice. A French patent has, however, been taken out (No. 400,921 of 1909) for sterilizing butter or other fats in this way. The substance is spread in a thin layer upon an endless band or revolving drum, the movement of which carries it past a series of lamps emitting ultra violet rays. (Simmons and Mitchell, Edible Fats and Oils, London, 1911, 43.)

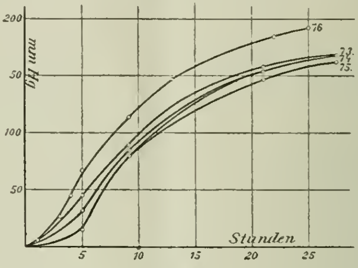

Fig. 4.

In discussing the various methods of sterilizing milk for use in margarine manufacture *Clayton* (J. S. C. I., 1917, 1206) observes that it should be possible to have a large scale ultra violet ray apparatus to sterilize milk at ordinary room temperature, just as Dornac and Daire sterilized water using quartz electric lamps. In any case, the future holds much in store for changing this part of a margarine process involving the incipient reduction of all the bacteria in the milk.

Petroleum Oil.

As previously stated, petroleum oil may be treated by powerful ultra violet rays to destroy its bloom or fluorescence (Ellis, U. S. patent 1,089,359, March 3, 1914). Some oils, by exposure, are reddened in color or otherwise slightly darkened. Other oils are bleached by such treatment. Petroleum oils which are intended to be used as lubricants and which may have gumming properties due to unsaturated constituents, are improved in quality by exposure to ultra violet light. Apparently polymerization occurs, resulting in the formation of saturated bodies. The oil may be exposed in an atmosphere of an inert gas. A high-voltage ultra violet lamp is used advantageously and if the heat which emanates from such lamps is very considerable, the oil may be cooled during the exposure. The treatment may be carried out as a continuous process by causing the oil to flow in a thin layer past the source of ultra violet light.

"Pre-vulcanized" Rubber.

Victor Henri is credited by *Helbronner* with being the first to expose rubber to ultra violet rays, carrying out vulcanization with films made from solutions of rubber, as early as 1909-1910. Rubber solutions which have been vulcanized by means of the ultra violet light, are stated by *Helbronner* (India Rubber World, Dec. 1, 1914, 130) to be insoluble in the same solvent when once they have been dried. This suggests that such solutions would be valuable for making patches on rubber (tires, inner tubes, etc.), for when once the patch had thoroughly dried the result would be the same as though it had been vulcanized. It was also suggested that crystals of sulphur should be used in this work and not flowers of sulphur ,or stick sul- also Compt. rend. 138. 1914, 1343 Chem. Zentr. 1914. 326; Koll. Zeit. 1913, 4; French patent 460,780 July 26, 1913.)

Albumen.

The action of ultra violet light on living cells has been studied by *Bovie,* (Science, 1913, 24), by its effect on certain constituents of protoplasm. Fresh egg albumen when exposed in a quartz tube at 10 cm from a quartz mercury vapor lamp at room temperature, began to show a feathery coagulum in 1 to 2 hours on the wall nearest the lamp, and after 35 hours was quite fully coagulated. The odor was peculiar and quite strong. When dissolved in water the same phenomena was noticed, the time being shortened, possibly due to better penetration. The coagulated material settled to the bottom of the tube. A solution of egg albumen which had been crystallized and not freed from ammonium sulphate coagulated more rapidly than fresh egg white. Solutions of crystallized egg albumen from which the ammonium sulphate had been separated by dialysis was more sensitive, some being coagulated when exposed in glass tubes which cut off the shorter waves. Ox-serum is coagulated when exposed to ulrta violet light in quartz tubes, but not in glass. The coagulated material resembles the material coagulated by heat in that it is insoluble in alcohol, water and dilute acids but is soluble in dilute alkalis.

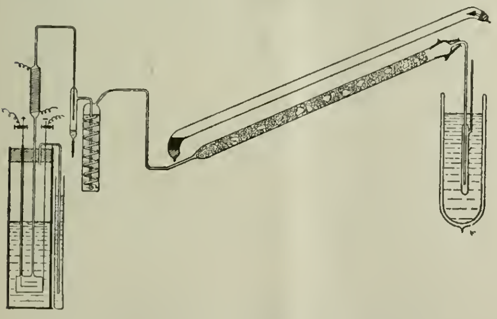

Fig. 5.—Genthe's Apparatus for the Condensation of Volatile Products of Drying Linseed Oil.

The effect of temperature on this coagulation was also studied by Bovie (Science, 1913, 374). When kept at O°C. no coagulation occured in a 5% solution of crystallized egg albumen after 35 hours exposure, but on warming a few degrees coagulation began, and tubes became turbid. If the temperature was again brought to O°C. the tube cleared up, that is the reaction was reversed. This phenomena occurred only when the temperature was reduced as soon as coagulation began. If a clear solution of the albumen which has been exposed to the light for some time at at O°C. is taken from the light and warmed, the coagulation occurs at about the same rate as though it were being exposed. It thus appears that the light produces some substance which causes coagulation but that at O°C. this substance is not capable of bringing about visible coagulation.

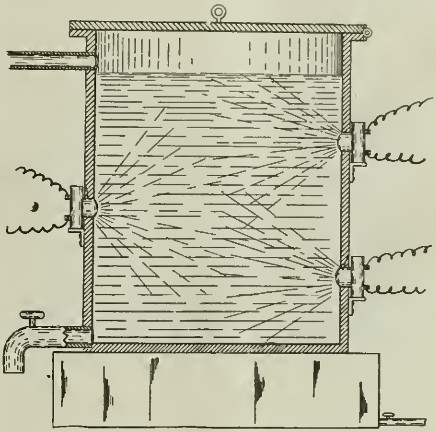

Fig. 6.—Minor's Apparatus for Bleaching Rosin.

Photographic Peculiarities of Alkaloids.

The behavior of a number of alkaloids as regards color when photographed under ultra violet light has been investigated by *Michand* (Science 1912, 415). Twenty-four samples of the powdered alkaloid were placed in boxes and photographed under ordinary light. Only one sample, berberine, showed black, the remainder showing white. Another photograph was taken using a quartz lens silvered on both sides. Berberine still showed black, eight samples showed white or nearly so, three showed gray .and the remainder were black or nearly so. No constant relation was found between this action and the chemical constitution, or of the physical properties, but it appears that the phenomena might be made use of in analytical chemistry.

Phosgene.

Wherly (Color Trade Journal 1918, 8) reports that experiments using ultra violet light for the production of phosgene by the union of carbon dioxide and chlorine have been successfully tried, but that the disadvantages on a commercial scale are manifest. Accordingly he does not believe the major portion of phosgene is manufactured with the assistance of either the actinic rays of the sun or those of ultra violet lamp. Thus it is more reasonable to suppose that by far the greater proportion of phosgene is manufactured by passing carbon monoxide and chlorine over platinized asbestos, charcoal or boneblack heated to redness.

Testing Ink.

Ultra violet light is used for the testing of ink in a rough-and-ready manner. In carrying out this test, streaks of the inks to be tested are placed on a sheet of paper along with a streak made with standard ink. The paper containing the streaks is then exposed to the rays of ultra violet light for varying periods, generally about forty-eight hours, and the relative effect noted. The method is therefore simply a comparison test with standard material (private communication from Percy H. Walker, Bureau of Standards).

Some Physiological Effects of Ultra Violet Rays.

It is commonly known that visible light is a sensation produced in our eyes by vibrations or waves in the ether of space. These waves are so exceedingly minute that their length from crest to crest is generally expressed in "Angstrom Units," each unit being one ten-millionth part of a millimeter.

Ether waves that measure 7600 to 6500 A.u. from crest to crest are manifested to the eye as red light, and those that measure 4200 to 3900 A.u. are seen as violet light. Between these extreme limits of wave-lengths we find visible light of all the colors in the rainbow, the blending together of which in daylight produces what is known as white light, being thus named because it shows all obpects in their true colors. Light that is artifically produced by flame or incandescence usually contains a preponderance of red and yellow rays, so that it does not show colors as correctly as does daylight.

Just as there are no sharp lines of definition between the different colored bands in the rainbow, so also do visible and invisible radiations gradually merge one into the other; and for convenience it may be roughtly stated that the average human eye perceives visible light between wave-leugths from 7600 to 3900 A.u.

Ether waves that measure more than 7600 A.u. (up to about 3,000,000 A.u.) constitute the infra red or heat rays, and those that measure less than 3900 A.u. (down to about 500 A.u.) are known as ultra violet rays.

We have, therefore, three divisions of radiation under consideration that are manifested respectively as infra red or heat rays, visible light, and ultra violet rays, the first and last being invisible. *Andrews* (General Electric Review, Nov. 1917, 9303) affirms that ultra violet rays are by far the most dangerous of all radiations to the eye, and the more so because they are not only invisible but also because we are unprovided by nature with any organ or sense for detecting them, so we know of them only by their effects. Fortunately the most deleterious of the ultra violet rays, i.e., those rays having a wave-length of about 3400 A.u. and less, are completely absorbed by a moderate thickness of almost any ordinary kind of glass, so that, when their existence is known, their harmful effects on the eye can be easily guarded against.

Precautions in Electric Welding.

The electric arc between carbon and iron, and iron and iron, according to Andrews, is one of the most prolific generators of these harmful rays, and operators on arc welding must necessarily be extremely careful in the employment of protective screens. Indeed, it may be stated that electric welding calls for eye-sight protection against intense heat rays, glare, flickering, and ultra violet rays. Notwithstanding this fact, however, complete immunity from bad effects to the eyes of operators can be assured by the proper use of protective lenses. The masks that are commonly used by operators not only are necessary for the protection of the face and neck from direct dangerous radiations but for the protection of the eyes from reflected ultra violet rays; these rays together with heat rays can be reflected from a surface in the same way as visible light, so that complete protection can only be assured by cutting off all light from the eye excepting that which passes through the lens.

For the same reason arc welding should not be carried on in an open shop or even behind screens closed only at the sides. The reflection of the vivid and flickering flashes from the walls and ceiling may easily affect the eyes of other operators who are not engaged in welding, and are therefore unprovided with any protective device.

The light from mercury-arc lamps is also rich in ultra violet rays, but when these lamps are made of glass the rays are absorbed, thus rendering the light harmless excepting for the glare. When made of clear quartz, however, they should never be used excepting when thoroughly screened by suitable glass shades, or very dangerous eye trouble will be sure to ensue, since clear quartz is transparent to ultra violet rays. Spectacles or eye glasses made with so-called pebble or crystal lenses (i.e., natural clear quartz) therefore afford no protection to the wearer; but the rays cannot pass through the ordinary lenses of plain clear glass.

Further Observations on the Protection of the Eyes.

Glasses for protecting the eyes from injurious radiations by *Coblentz* and *Emerson* (U. S. Bur. Standards, Techn. Paper No. 93, 1917; J. Frank. Inst. 183, 629, 1917). The general characteristics of certain newly developed glasses sometimes used for protecting the eye from radiant energy, are given. Because of the difficulty in reproducing the same color in different melts, no attempt is made to give specific data on the transmission for a given thickness of glass, for in order to be exact it would be necessary to examine samples from each melt. The conclusions drawn are representative of an extensive group of glasses available for protecting the eye from (1) the ultra violet, (2) the visible, and (3) the infra red rays. For protecting the eye from ultra violet light, blacks, amber, green, greenish yellow, and red glasses are efficient. Spectacles made of white glass afford some protection from the extreme ultra violet rays which come from quartz mercury vapor lamps and from electric arcs between iron, copper or carbon. The vapors from these arcs emit but little infra red radiation in comparison with the amount emitted in the visible and in the ultra violet. For shielding the eye from infra red rays, deep black, yellowish green, sage green, gold plated, and plush green glasses are efficient. For working near furnaces of molten iron or glass, if considerable light is needed, a light bluish green or sage-green glass is efficient in obstructing the infra red rays. For working molten quartz, operating oxyacetylene or electric welding apparatus, or other intense sources of light, it is important to, wear the darkest glasses one can use whether black, green (including gold-plated glasses), or yellowish green, in order to obstruct not only the infra red but also the visible and the ultra violet rays.

The efficiency with which the eye is protected from ultra violet rays is discussed by *Bell* (American Academy of Arts and Sciences, 1911, 671), who states that under ordinary conditions chemical tests have shown that no permanent effect is caused by exposing the eye to ultra violet rays. In cases where the exposure is severe, lenses should be provided, but the choice of glass is a matter of taste, ordinary optical glass being almost opaque to ultra violet rays. Of the colored glasses, ordinary commercial amber glass seems to be as effective as special glasses, although in the lightest tints, traces of ultra violet will pass, but if the color is deep enough to materially cut down the visible light these traces will disappear. A number of spectograms are shown illustrating the effectiveness of various glasses.

Steinmetz (Radiation, Light and Illumination) observes that since ordinary transparent glass is opaque to ultra violet rays, persons exposed to such rays should protect themselves by the use of glass either in the form of protecting tubes around the source of light or else by wearing spectacles. Very intense ultra violet radiations, however, pass to a greater or less degree through ordinary thin glass. The thickness of the protecting globes therefore should be regulated. Red glass is considered to be more opaque to ultra violet radiations than other varieties. He states that blood is practically opaque to the rays and on exposure of the body thereto, the rays penetrate but slightly beneath the surface where they are absorbed by the blood. He also observes that complete recovery from ultra violet burn may be extremely slow, taking months or even years for practically complete recovery and in some cases where the burn has been extremely severe some after effects, such as, for example, abnormal sensitivity to radiations of short wave length, may be practically permanent.

Simple Tests for Ultra Violet Rays.

Ultra violet rays produce the effect known as "fluorescence" in certain chemical substances. When these substances are seen by a mixture of visible and ultra violet light, such as that emitted from the iron arc, their apparent color is changed. Thus, soda salicylate in tablet form or in powder changes its color from pure white to a bright blue while it is illuminated by the mixture of rays, unless the visible light is so strong that it overpowers the fluorescent color. A high-tension disruptive discharge of electricity between iron points is an excellent source of ultra violet rays for producing fluorescent effects, because it emits an excess of ultra violet rays as compared with its visible light. A pebble or crystal lens can be readily distinguished from one of plain glass by this light, for if the lens is interposed between the iron spark discharge and a fluorescent substance, such as soda salicylate, the blue color will immediately vanish and the salicylate will assume its natural white: but if the lens is made of quartz, the blue fluorescence will remain unchanged.

Fig. 7.—(A) "Iron Spark" Spectrum. (B, C, D) Same, Photographed Through Various Colored Glasses.

Absorption Effects of Color Screens.

Fig. 7 (according to Andrews, *loc. cit.*) shows the full spectrum of the visible light emitted to a disruptive iron spark discharge and also the absorption effects of various colored glasses when interposed between the spark and the photographic plate on which the spectrum is recorded.

Fluorescent Effects.

Andrews (General Electric Review, April, 1916, 318) gives the following list of a few fluorescent substances, most of which are readily obtainable, and which appear white or nearly so under visible light, but which assume bright colors under the invisible ultra violet rays:

Natural calcite from Franklin Forge, N. J., and other localities	Red
Barium sulphide, all tints of	Orange
Cadmium compounds	Yellow
Willemite, natural and artificial	Green
All salts of salicylic acid, such as soda salicylate, etc.	Blue
Some compounds of calcium	Violet

It is a remarkable fact that, broadly speaking, many substances that are quite transparent to visible light are entirely opaque to ultra violet radiation, while other substances are equally transparent to both. Thus glass, mica, gelatin and celluloid even in very thin sheets are quite opaque to ultra violet rays, but clear rock-crystal or quartz, fluorite and selenite are all about equally transparent to visible light and invisible ultra violet rays.

These curious properties may be readily demonstrated thus:

If ultra violet light is directed on a lump of willemite, the latter will glow with a beautiful green fluorescence. If a thin plate of glass or clear mica is now placed between the source of light and the willemite, the green fluorescence of the latter will instantly vanish, and it will appear in its natural color as seen by daylight or any ordinary artificial light. If now a plate of clear quartz or selenite is substituted for the glass or mica, the willemite will continue to glow with its characteristic green fluorescence. It is thus made evident that the glass and mica are opaque to the ultra violet rays which produce fluorescence, while the quartz and selenite are transparent to them. This experiment may be tried with any fluorescent substance other than willemite with similar results.

Lenses made of rock crystal (clear natural quartz) may be used to concentrate the ultra violet rays from iron spark or other forms of ultra violet light apparatus and thus enhance their fluorescent effect.

Some substances, such as barium or calcium sulphite, continue to glow for a time after the exciting ultra violet rays have been cut off, thus illustrating the phenomenon of *phosphorescence* which is simply a persistence of fluorescence.

Steinmetz, (Radiation, Light and Illumination) in discussing the effect of ultra violet rays upon certain dyes and colors, states that substances such as rhodamine and uranine when exposed to ultra violet rays, viewed through a red glass which cuts off the rays of different wave lengths, show a fluorescence in dilute solutions. Weak solutions of the dyes in water, samples of cloth which had been dyed and varnishes containing these colors all showed red fluorescence. The concentrated solutions and the dry colors show no such phenomena.

Portable Military Sterilizer.

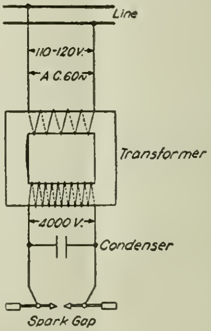
A complete portable ultra violet water-sterlizing apparatus is in use by the Austrian army, (Scientific American, 1917, 515). The plant consists of a small gasoline engine coupled to a rotary pump, and also to a dynamo for generating current fo rthe ultra violet lamp, a sterilizing tank, a rapid filter, hose connections, etc. The apparatus is also fitted with automatic valves so that when once started the machine will need very little attention.

Sterilizing Water Coolers.

A sterilized bottled water service has been established in Chicago by the *Rayvio Water Co.*, (Engineering Record, 1912, 110). The apparatus for sterilizing the water consists of a Cooper Hewitt quartz mercury vapor lamp suspended in a tank 2½ inches above the water. The twice filtered water is passed through the apparatus and bottled, the bottles being sealed with sterilized tin foil, which is punctured by a wire spear which is in the cooler. This delivers sterile water directly into the cooler; which in turn is sterilized every few days by a portable ultra violet light sterilizer.

Municipal Water Purification.

The sterilization of water by the ultra violet ray, including types of apparatus, current consumption and efficiency, is considered by *Rideal* (Water Supply, p. 207; published by Crosby, Lockwood & Son, London, 1914). Arons is stated to have been the first to make use of glowing mercury as a source of light. His apparatus consisted of a glass tube one meter long containing a small amount of mercury. Rideal notes that a number of French cities make use of the ultra violet light to purify their water supplies.



(Courtesy General Electric Co.)

Fig. 9.—Diagram Showing Connections, "Iron Spark" Apparatus.

In discussing the possibilities of municipal water purification by means of ultra violet light, it has been remarked (The Surveyor, London, 1914, 321), that it is somewhat surprising that no more definite information is available regarding efficiency and cost of operation of large installations. Many installations were stated to have been made but no data was available except perhaps as to first cost of installing.

Iron-Spark Apparatus.

The high tension disruptive electric spark between iron terminals is very rich in ultra violet radiation covering about 80 per cent of that part of the spectrum which is useful for producing fluorescent effects. A number of metals other than iron have been used for electrodes, such as zinc, cadmium, magnesium, nickel, cobalt, etc., but, while some of these produce more intense radiation than iron in certain regions of the ultra violet spectrum, they fail to produce any rays of useful power in other regions, whereas iron shows a more uniform distribution throughout the entire range. Iron electrodes have therefore been adopted for use in an outfit recently designed especially for the production of fluorescent effects, described by *Andrews* (General Electric Review, April, 1916, 319.)

This outfit comprises:

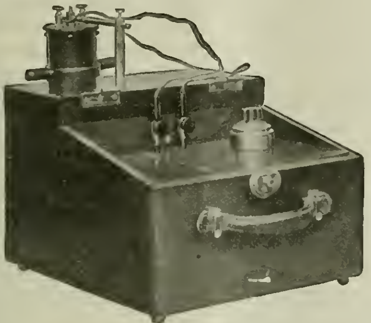
1. A small transformer that steps up 60-cycle, 110-120-volt alternating current to about 4000 volts.

2. A suitable condenser.

3. An adjustable spark gap with removable iron terminals, the whole being protected in a chamber of insulating material.

4. Sundry fittings with connecting cords and plugs.

All of the above parts are fitted into a box for convenient transportation, and it is only a few minutes' work to take out the spark gap, fit it in position and connect the apparatus to any suitable current outlet. As this outfit only uses about 250 to 300 watts it can be safely connected to any alternating current lighting circuit. The iron electrodes are enclosed in a small cylindrical chamber of insulating material, open at one end only, and having the insulated heads of adjusting screws projecting outside, by which the operator is able to regulate the frequency of the spark from 120 per second (with 60-cycle current) up to ten or twenty times that value. This small outfit produces an abundance of ultra violet radiation with which a number of very interesting fluorescent effects may be produced. The rays that are produced by the iron spark as above described naturally contain a large proportion of visible light, and in certain cases, when a substance may show only a weak degree of fluorescence, the color of the latter may be masked or overpowered to some extent by the visible light component.



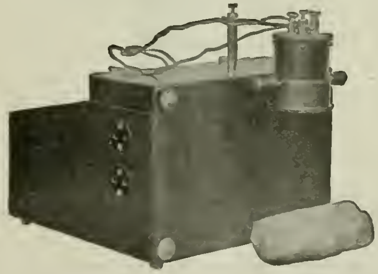
(Courtesy General Electric Co.)

Fig. 9.—Front View, Portable "Iron Spark" Apparatus.

The following simple experiment showing the specific action of ultra violet rays is suggested by the makers of this type of iron spark apparatus: Support a sheet of photographic printing paper, such as "Solio" close under the hood—then turn on the current for a few seconds and the paper will be blackened. To show that it is the invisible ultra violet rays that have produced this blackening, and not the visible light of the discharge, repeat the above experiment, but cover half the exposed circle of solio paper with a sheet of clear thin glass. After exposure it will be seen that the portion of the paper under the glass is unaffected—or very slightly colored, whereas the unprotected half will be blackened. Thin plates of clear quartz or selenite being transparent to the actinic ultra violet rays, the photographic paper will blacken rapidly if plates of these substances are used instead of glass or mica.

Electrode Materials for Ultra Violet Radiation.

A spectroscopic investigation of some sources of ultra violet radiation in relation to treatment by ultra violet rays has been made by *Schunck* (Lancet 1917, 996; Chem. Abs. 1917, 2679) using a quartz spectograph. The sources of radiation examined consisted of metallic electrodes of pure tungsten, molybdenum and iron; one-fourth inch carbon rods impregnated by boiling in solutions of sodium tugstate, uranium nitrate, ammonium molybdate, and titanous chloride; and one-half inch cored carbons filled with pitch blende, haematite, wolfram (75% WO_3, 20% FeO, and 5% MnO) an ore of tungsten, and pure tungsten and molybdenum (99%) in the form of powder, together with Simpson electrodes which are said to consist of wolfram. The most intense and richest source of ultra violet radiations is obtained with tungsten metallic electrodes. The molybdenum spectrum is of a similar character but not so intense throughout, extetnding to U. 2190 but losing in intensity at U. 2300. The iron arc spectrum is very rich in ultra violet radiations but, though containing some dense groups of lines, it is not so uniform throughout as that of tungsten and it extends only to U. 2250. Of the cored carbons, the tungsten powder gives a less intense spectrum than the tungsten electrodes; haematite is almost equal to these electrodes with the advantage of steadiness. The impregnated carbons are much more intense in the spark than in the arc. Uranium nitrate, and ammonium molybdate impregnations give a strong, almost continuous spectrum extending to U. 2300 without much loss of intensity. It seems probable that the radiations of therapeutic value lie between U. 3000 and U. 1850, and an attempt is now being made to determine by spectroscopic means which part of this region has the greatest therapeutic efficiency.



(Courtesy General Electric Co.)

Fig. 10.—Rear View of "Iron Spark" Apparatus.

Magnetic Deflection of the Mercury Arc.

An arrangement by means of which the light of a mercury-vapor arc is obtained free from the effect of absorption is claimed by *Kerschbaum* (U .S. Patent 1,118,868, Nov. 24, 1914). In lightly loaded lamps the illuminating vapor uniformly fills the entire cross-section of the tube between the electrodes, but when there is an increased load, and therefore higher temperature, the radiant vapor retreats from the walls of the surrounding tube, and forms an intensively radiant thread of light located in the axis of the tube, surrounded by comparatively weakly illuminating mercury vapor. The light of the bright radiant axial thread, in order to be able to issue from the lamp, must first penetrate the envelope of vapor and undergo absorption. To obviate this absorption effect, the temperature of the envelope is reduced, and hence the concentration of the absorbing vapor is diminished. This can be effected by cooling outwardly, but owing to condensation of mercury vapor, a coating of mercury forms on the entire inside wall of the lamp and allows almost no light whatever to issue. To prevent condensation of the mercury vapor, the arc is deflected toward one side of the tube of the lamp by means of an electro magnet, thus raising the temperature of the tube at the place where it is applied and burning for itself an aperture in the film resulting from condensation. The light of the deflected radiating arc will issue through this aperture without having penetrated an absorbing layer of mercury vapor. *Fig.* 11 shows the form of construction of this apparatus.

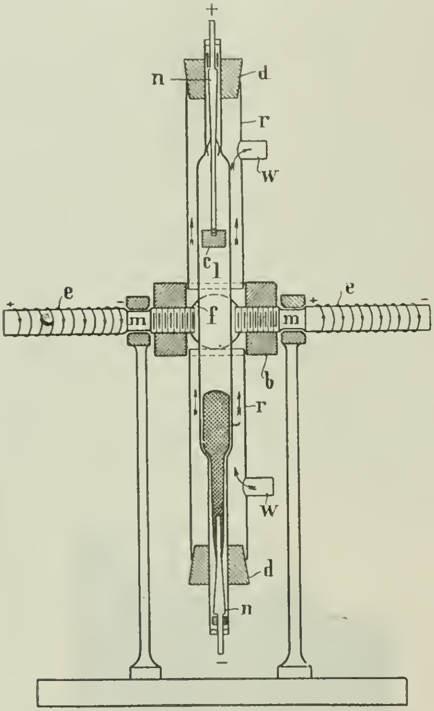


Fig. 11.—Kerschbaum's Apparatus for Magnetic Deflection of Mercury-Vapor Arc.

The brass block (b) has a vertical bore; into this are soldered two tubes (r) having branches (w) for receiving and discharging the cooling water. Into this vertical cooler is inserted a quartz mercury-vapor lamp (l), which is fastened above and below by means of bored rubber stoppers (d). The quartz lamp is a vertically burning lamp, which is of the simplest and most compact construction possible. As leading-in members for the lamp, ground-in nickel-steel pins (n) serve. Only the metal of the lower electrode (cathode) is mercury, the anode is a piece of carbon (c) screwed on the end of the upper nickel-steel pin. The brass block (b) has, in addition, two lateral, horizontal, threaded bores. By means of these apertures the ends of two iron rods (m) are screwed up close to the wall of the lamp; over these rods are pushed coils of wire (e). Each of the two coils has 200 turns of covered copper wire of ½ohm. resistance; the current employed is 2-3 amperes. The electromagnets so formed produce lines of force at right angles to the axis of the lamp. The block (b) has another horizontal bore (f). This passes through only the rear half of the block and can be closed by a quartz plate. When the lamp is burning and the electromagnets are so connected that they deflect the arc to the rear, the light will issue through the bore (f) and enclosing quartz plate. The arc is drawn by rotating the lamp into its horizontal position.

The exposure of many elements to the action of ultra violet light causes them to give off electrons, and the more electro positive the element the more easily will the electron be split off. Alkali metals are most sensitive, yet electro negative oxygen appears to be ionized. To further investigate this subject, *Ludlam*, (Philosophical Magazine, 1912, 757) made experiments on chlorine, the most electro negative element upon which experiments can be made. It was concluded from these experiments that pure chlorine is not appreciably ionized, that traces of chlorine increase the ionization of ordinary air, and that chlorine in considerable quantity reduces the ions and muclei otherwise formed in air.

While investigating the action of ultra violet rays under various conditions *Bichat* (The Electrician, London, 1888, 739) observed that if a conductor connected to an electrometer was exposed to ultra violet rays the electrometer shows a positive potential or in other words the air surrounding the conductor becomes negatively charged.

Temperature-Coefficients for Different Wave Lengths.

The intensity of photochemical action on a mixture of chlorine and hydrogen prepared electrolytically from hydrochloric acid was measured by *Padoa* and *Butironi* (Gazz. Chim. Ital., 1917, 47; J. S. C. I., 1917, 961) who determined the contraction in volume after exposure at definite temperatures in white, ultra violet, and colored light. According to Bevan (Proc. Cambr. Phil. Soc., 12, 398) the temperature coefficient for an interval of 10° C. in the case of a mixture exposed to white light is 1.21. In the determinations of Padoa and Butironi the following coefficients were obtained: In white light, 1.29; green light (nickel sulphate solution screen), 1.50; blue light (copper sulphate screen),

INORGANIC CHEMICAL SYNONYMS

A Novel Work of Reference for Student and Chemist

By Elton R. Darling*

Although Intended Primarily for the Student, It Is Believed That the Following Compilation of the Various Terms Employed to Designate Inorganic Chemicals Used in the Industries, Will Prove a Convenience to the Experienced Chemist. The Writer Claims No Originality for the Synonyms, but Only the Bibliographical Research of the Material at Hand. Part III Will Appear in the Next Issue.

PART II

Antimony. 120.2

Specific gravity 6.62, fuses at 450° C., melting point 630° C., and has a boiling point of 1440° C. It is trivalent in the antimonious condition and pentavalent in the antimonic.

Its name is derived from the Greek word *anti*, meaning against, and *monine*, the French word for monk. The reason for this was that a number of monks were poisoned by antimony compounds.

No doubt our knowledge of antimony would be much clearer had not the Alexandrean library been destroyed by the Romans. The true discovery of the metal cannot honestly be attributed to any one man.

Antimony is spoken of in the Bible in the book of Hebrews, and again in the second book of Kings. Dioscorides speaks of it as used by the women of his time as an eye-expander. The alchemist Geber was familiar with it. There is little or no doubt that the metal was known long before Valentine's time. Basil Valentine was, however, the first man to give any treatise on the subject. It is believed that his works were the result of a study made of the material scattered throughout the literature of that time. He does, however, credit himself with the discovery of the metal.

Mordant Salts

Arsenic 75.

Specific gravity 5.9. It has a melting point of 850° C., but sublimes at 554° C. without fusing. It is trivalent in the arsenious condition and pentavalent in the arsenic.

Orpimint and realgar were both known to the ancients. Aristotle and Theophrastus both wrote of these products, but made no distinction between them.

The Greek alchemist Olymipiodonis made mention of the white oxide in his writings. Albertus Magnus knew of the properties of arsenic and wrote of its being volatile. He was the first to give any reliable information concerning the element.

Barium 137.37.

Specific gravity, 3.78; fuses below red heat, melting at 850° C. and boiling at 950° C. It is divalent.

Barium first became known through one of its compounds, heavy spar. A Bolognese shoemaker, V. Cascionolus, in 1602, noticed that when this product was heated with barbonaceous matter it became phosforesent. To this was given the name lopis solis, Bolognian phosforous, and Boronian phosforous. Marggraf in 1750 supplied the knowledge that it contained sulfuric acid.

In 1774 Scheele, during some researches on the black oxide of manganese, found it to contain a new earth. This product with sulfuric acid formed a compound which was insoluble in water. He did not carry out any further work on it. Gahn in 1776 showed that it was the same compound found in heavy spar.

Guyton de Moroeau in 1779 gave it the name of barote, which was changed to baryta by Lavoisier. The metal was first isolated by Davy.

Bismuth 208.0

In the writing of the alchemists of the thirteenth century mention is made of the word Marcasite, which at that time referred to bismuth. As early as the time of Paracelsus an attempt was made to classify it. He placed it with the semi-metals. Agricola stated that it was a true metal but required the presences of tin. Libavius associated it with antimony, Lemery with zinc and Basil Valentine between tin and lead.

But our true knowledge of the properties and reactions of bismuth was given to us in 1739 by Pott and Bergman.

It has a specific gravity of 9.75, fuses at 264° C.; melting point, 270° C., and has a boiling point of 1420° C. In the bismuthous state it is trivalent, and in the bismuthic state it is pentavalent.

- Basic Bismuth Carbonate 526.02

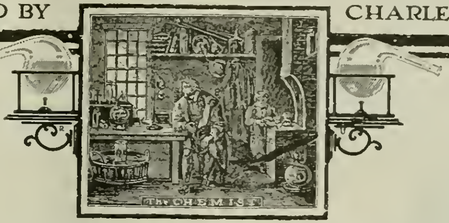
CHEMICAL INVESTIGATION
EFFICIENCY & CONTROL

CONDUCTED BY CHARLES B. DAVIS, F.C.S.



ALL classes of work covered by the following subjects will be done for readers of "The Chemical Engineer" through this department by Mr. Davis: Special research of every description; analysis and reproduction of any commercial product; prevention of waste and utilization of by-products on the most economical basis; valuation of raw materials; food analysis, and disputed points in regard to adulteration, labeling, and the enforcement of pure food laws; bacteriological and enzymatic examinations, including fermentation tests, pure yeast cultures, beverages of all kinds; development of chemical inventions and industrial processes; examinations and advice on special machinery.

Inquiries of a minor character will be answered on this page, while major matters involving personal investigations, analyses, etc., will, if desired, be treated confidentially through the mails. All questions, materials for analysis, or letters leading to the opening of negotiations for special work will receive prompt attention if addressed to

CHARLES B. DAVIS.
Care of "The Chemical Engineer," 118 East 28th Street,
New York City.

Y. A. N.—It was in the Jingera Mountains, New South Wales, that a rich discovery of bismuth, wolfram and molybdenite was made.

The reefs are from three to five feet wide. A company is being formed to develop these properties.

S. A. A.—The water soluble potash recovered from the 200 blast furnaces is as follows.

	per year. Tons of potash
Flue dust	6.5
Tube dust	180.0
Spent liquor	650.0
Ashes	780.0
Total tons K_2O	1,616.5

Five days after I receive your samples the full report will be rendered.

E. A. W.—Have received the samples of Charcoal, Acetate of Lime, Tar, Wood Alcohol and Crude liquor, also your data as to the quantities you are recovering, and will proceed at once with the investigation.

As requested by you, I will include in my report a sketch of the "chemical plant" as found necessary from the results of my experiments.

I would strongly advise that you reduce your output as agreed, until the completion of this investigation.

W. B. C.—The coal you forwarded me for analysis contains 1% of ash. The melting point of this ash is very low, and since the fusibility of an ash has a very important practical bearing on the use of coal, I would recommend that you immediately notify your dealer to remove it from your premises or deduct the loss in heating value from the bill.

T. W. S.—"Crude Solvent Naphtha," "Solvent Naphtha" and "Heavy Naphtha" are all products of coal tar distillation.

The "Solvent Naphtha" will best suit your purpose.

B. C. K.—From the analysis of the transparent tissue you advised me to obtain in the open market I will state that it is a product of an evaporation of a solution consisting of cellulose esters, with amyl butyrate.

I can supply you with an outline of the necessary equipment for the production of the material.

R. P. D.—As I have mentioned many times in these columns, an analysis is by no means a working formula. On this account you have been subjected to the trouble and expense you mention.

C. C.—A new method for the preparation of Uranium Oxide will be found on page 109 of the May issue of this journal.

This method is covered by two U. S. patents granted to C. L. Parsons, but has been dedicated for the free use of the people, and you can therefore make free use of it. If you experience any difficulty in the manipulation of the process I will be pleased to aid you in every possible way.

G. A. H.—Am pleased to hear that you have overcome your troubles as to reaction, color, mold growth and moisture content.

The samples you are now sending will be reported on as soon as possible.

Charles B. Davis.

Those whose inquiries to this department have not as yet received attention must bear in mind that unless replies by mail are specifically requested, communications can only be considered in the order of their receipt.—Editor.

Link's Stationary or Superimposed Water Still

There has recently been placed on the market a further development of the Link Still, the "Link Stationary or Superimposed Water Still," which appears to be the only dependable still for scientifically correct distillation of water. Two illustrations, Figures 1 and 2, show respectively exterior and interior.

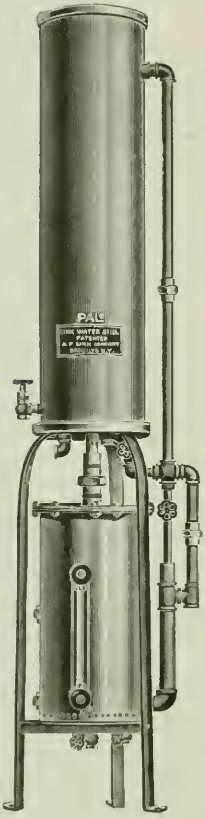


Fig. 1.—Exterior View of the Link Water Still.

The Link still is operated by steam at pressure between 15 and 150 lbs. This is admitted to the coils and has its return outlet at the bottom of the evaporator. The steam inlet and outlet are firmly secured with suitable lock nuts.

The construction of the Link still, in regard to material and workmanship, is of the best. The parts which come into direct contact with the vapors or distilled waters are made of copper and brass, heavily tinned with only pure block tin, the bath dipping process having been employed. This means durability and reliable service. All parts are easily taken apart without dismantling the whole.

The gas vent tubes extending to the top of the condenser act as a reliable gauge for the operator regarding the amount of raw water to be fed to the condenser. Should water vapors escape through these vent tubes, it is proof that the water in the condenser is too hot and more raw water must be fed. Once the flow is regulated no further attention is required.

The Link still is so constructed that the condenser can be taken down or taken apart (for cleaning) without dismantling the evaporator. Likewise the latter may be taken out without interfering with the condenser by simply disconnecting the two union joints, one between the evaporator and condenser and the other on the overflow pipe.

For flushing the condenser as well as the evaporator a valve is provided at bottom of each. This method of flushing entirely prevents scaling and the highest efficiency is maintained all the time. At the bottom of the evaporator there is a separate valve for flushing the sediment cup.

The raw water is fed to the condenser through the valve shown on the left (Fig. 2). The evaporator is constantly supplied with pre-heated water through the overflow pipe. This supply can be regulated by an intermediate valve to keep the water in the evaporator at proper height. All surplus overflow runs to waste.

Chemists have always had unpleasant experiences in analytical, research, material testing, or production to control work, which have in many instances been traced to the use of imperfectly distilled or merely filtered water.

The Link still embodies many innovations, some of which have entirely revolutionized the old time method of distilling water. The novel feaures of the well known and efficient "Link automatic and portable water still" have been embodied in this larger apparatus and have proven entirely successful from every point of view.

The evaporator is at a practical distance below the condenser. The steam coils are enclosed in an annular mantle, which terminates in a sediment receiver, or cup. The latter is provided with a deflector hood and baffle to prevent the sediment or particles of solids from leaving the sediment cup and returning into the boiling water.

This arrangement also keeps the water in rapid circulation in the direction shown by the arrows (Fig. 2). Also soon as boiling commences, the water takes an upward motion, discharging into the cup, where all solid matter (sediment) is gradually gathered and remains below the baffle. The sediment cup can be drained at any time during operation without interfering with the process of distillation.

In other stills it often occurs that particles of solids entrail into the condenser, especially when these stills are worked to full or over-capacity. In the Link still this is prevented by the separator dome near the cover. The vapors, which ordinarily entrail impurities into the condenser, must pass through a series of horizontally located holes in the separator dome and these impurities with the saturated vapors are returned to the boiler. Therefore only dry and pure vapors are permitted to rise through the vapor tube to the condenser. To prevent condensation in this vapor tube an air-insulation space has been provided and the dry vapors reach the condenser sections through the distribution dome. The number of condenser sections varies according to capacity and size of the still.

All the condenser sections terminate into one manifold with one joint outlet for the distilled water at or near the bottom. The outlet is provided with standard size thread for attachment to pipe the distillate away. The outlet is fastened to the bottom with lock nuts and can quickly be detached for occasional cleaning.

Through the onrushing vapors in the vapor tube, the raw water in the condenser near the top becomes quickly heated and passes in this condition through the overflow pipe into the evaporator or to waste. Moreover, as in other stills, a certain amount of ammonia and other noxious gases escape before passing into the overflow pipe. Thus the raw water, partly freed from noxious gases, runs into the evaporator at nearly boiling point, which insures quick and uninterrupted evaporization and effects great economy.

The vapors rising through the moisture separating dome still contain the left-over ammonia and other noxious gases. On their course through the condenser the vapors are pressed against a series of deflectors or baffles. When condensation sets in, the ammonia and other noxious gases are released and escape according to their specific gravity upward through the vent holes, remote from the distillate.

The distilled water flows from the condenser chemically pure and at a temperature as cool as the raw water fed to the condenser. The distillate is therefore immediately available for use. Owing to the large condensing surface, only a small amount of raw water is required as compared with other stills. This results in saving of water and heat.

Another new and important feature in the "Link Still" is the introduction of practical aeration of the distilled water for drinking purposes. This aeration is based on the injector principle. The free air is syphoned through the air intake and in passing between the vapor tube and gas vent neck is rapidly heated and sterilized. It then mixes with the vapors, is absorbed in the process of condensation and is held by the distillate on its downward course during cooling. Through the closing of the air intake a non-aerated, chemically pure distillate is produced.

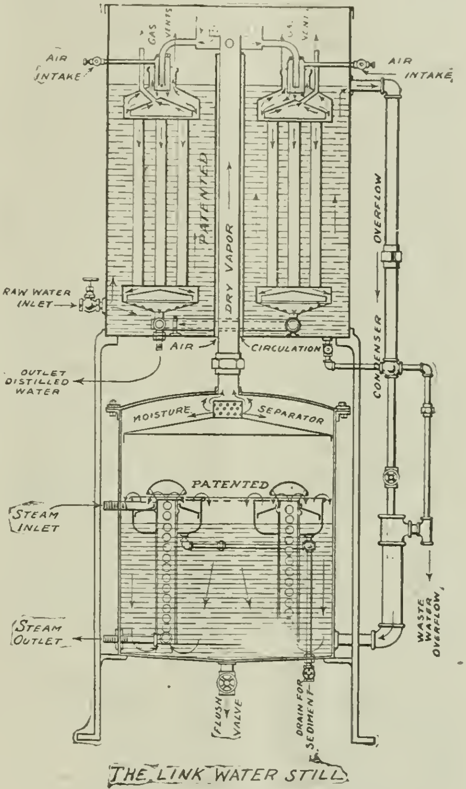

Fig. 2.—Diagram Showing Operation of the Link Still.

The stationary or super-imposed type of "Link Still" is manufactured in various sizes producing 5 gal. to 100 gal. per hour of distilled water.

The floor space required for these stills is comparatively small; the 10 gal. capacity p. h. still requires only 18 inches square.

This patented still has been developed by the A. P. Link Company, and the sole selling rights are in the hands of the Palo Company, 90-94 Maiden Lane, New York City.

West Coast Glass Co.

Glassware of various kinds will be manufactured by the West Coast Glass Co., Inc., Los Angeles, Cal. The capital is $100,000 and the incorporators are H. R. Jones, Frank C. Ford, Arthur White, G. H. Bessemyer and R. D. Tiffany.

An Unusual Design for Distillation and Evaporation.

Those who have to deal with the distilling of sea or other water or with evaporation problems of almost any kind will be interested in this design of Lillie Evaporator, now being built by the Wheeler Condenser & Engineering Co., of Carteret, N. J. It is, as will be noted, a modification of a regular Lillie sextuple effect sea water distilling apparatus. Two of these now under construction are to be operated by steam up to 60 lb. per square inch gauge pressure, or at any lower pressure.

The point that will catch the veteran's eye is the employment of four condensers, side by side, as shown in the illustration.

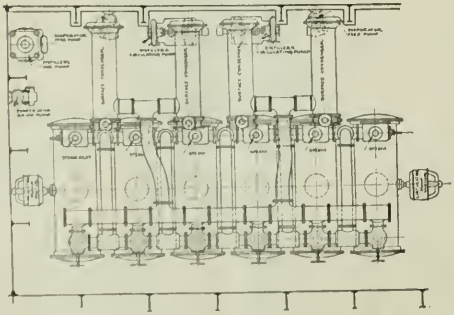
This unusual arrangement of condensers permits seven different combinations of operation, as follows:

(1) It may be operated as one single eeffect or more single effects;

(2) It may be operated as one or more double effects, with vapors reversible in each;

(3) It is possible to operate it as a triple effect, or as two triple effects, with vapors reversible in each;

(4) It is impossible, of course, to operate it as two quadruple effects, but every effect may be utilized by grouping as one quadruple effect and one double effect, in both of which thre vapors are reversible;



The Lillie Evaporator.

(5) It may be operated as one vapor reversible quadruple effect with both end effects or either end pair of the section cut out;

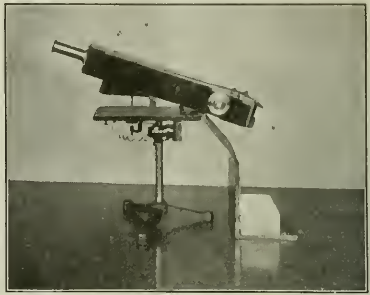
(6) With one effect at either end cut out, it may be operated as a vapor reversible quintuple ffect;

(7) Lastly, it may be operated as a vapor reversible sextuple effect.

It is evident that should a mishap occur at either end, in the middle, or anywhere else, there is little danger that this evaporator will be put out of commission entirely.

The Hess-Ives Tint Photometer.

The instrument illustrated below is used for accurately determining and recording color values by numerical expressions without involving a personal element. The basis of comparison used is thoroughly scientific and not arbitrary. It is applicable to solids or liquids using either transmitted or reflected light. Two magnesium carbonate blocks, the purest white known, are used to furnish the bands of comparison in the two halves of a circular matching field which is similar to that of a polariscope. In order to secure a standard source of light, both day and night as well, in all countries, a "Daylight" lamp of special type has been designed and found to produce uniformity throughout. This enables the operator to check, concordantly, readings taken in laboratories of other countries and regions, which feature alone very much assists the chemist who is required to check up color work obtained in other laboratories.



Hess-Ives Tint Photometer.

The instrument is set in adjustment for use as shown above. The rays of light from the illuminant fall on the magnesia blocks. The light is reflected from these blocks into the body of the photometer through two adjustable slits, one opened and closed by a milled head screw and the other by an actuating lever shown on top of the instrument. In the body of the instrument the light passes through a revolving optical mixing wheel which is made up of a series of lenses and is revolved by means of a small motor. The function of this mixing wheel is to spread the light evenly across the respective half fields which are presented to the eye when looking into the telescope, and which are divided by a vertical hair line. One field is illuminated by the standard white magnesia block and the other by the sample to be tested, which is placed on the right hand block.

The photometric measurements are made through three color-screens, pure red, green, and blue. These screens color both circular fields, but one half-field is darker than the other, due to the effect of the sample. The fields are then brought to the same depth of color by moving the actuating lever over the scale, which closes the aperture illuminated by the magnesia block. When the fields are matched the scale is read off and the expressions recorded.

Special pamphlets fully describing and illustrating this new color instrument have been published by the Palo Company, 90-94 Maiden Lane, New York.

NEW PUBLICATIONS

The Dyestuff Situation in the Textile Industries

The most recent number of the tariff information series of the United States Tariff Commission is a pamphlet on "The Dyestuff Situation in the Textile Industries, 1913 and 1916." In it are presented the results of an inquiry sent to 77 companies who are representative consumers of dyestuffs in the textile industries. Of the companies reporting, 23 were engaged in cotton manufacture, 25 in wool manufacture, 8 in silk manufacture, and 21 were independent dyers and finishers. The cotton manufacturers were the only group reporting the use of smaller quantity of dyestuffs in 1916 than in 1913. A substantial increase as reported by the other groups would seem to indicate that by 1916 the domestic manufacturers of dyestuffs had made considerable progress in replacing foreign-made dyes with those of American manufacture.

The increase in the costs of the individual dyestuffs is particularly striking. In some instances alizarin and anthracene colors were purchased in 1916 at prices 20 to 30 times those paid in 1913. The total value of all the dyestuffs consumed by the 77 companies in 1916 was approximately four times the value of the dyestuffs consumed in 1913. The greatest shortage occured among the dyes which were not made in this country before the war, particularly in the case of synthetic indigo and the vat dyes from anthraquinone needed by the cotton dyer and the alizar in colors needed by the wool manufacturers. Vegetable indigo and natural dyes such as logwood and fustic came into importance as substitutes for the coal-tar derivatives. American-made sulphur colors were given a wide application and certain gallocyanine dyes were developed to replace the imported alizarin and anthracene blue.

The opinions of the textile manufacturers as to the operation of the present dyestuff schedule of the tariff and their suggestions for changes to meet the conditions after the war form what is perhaps the most interesting part of the report. These opinions, which are quoted without the indorsement, criticism, or comment of the Tariff Commission, indicate that on the whole the textile consumers of dyestuffs will give the new American industry the support and patronage that will insure its continuance after the war.

"Comparative Tests of Laboratory Porcelain Ware."

Under the above title a new publication has just been issued by the U. S. Bureau of Standards (Technologic Paper No. 105) which should be of genuine interest to chemists and all laboratory workers. The report, which is in the form of an eight-page pamphlet, was prepared by C. E. Waters, a chemist connected with the Bureau, and recognition is made of the fact that results could not be made as significant as those obtained from tests of glassware. The paper contains a brief outline of the comparative tests of two American, two German, and one Japanese ware; it shows that only the last, and one German make, stood up well when suddenly heated or cooled. Cracks in the glaze formed under the tongs when hot pieces were picked up. At times the dishes broke. The solubilities in various reagents showed that all kinds were about equally resistant. The stains caused by ignition with ferric oxide are superficial and do not depend upon the formation of easily soluble silicates.

The paper is now ready for distribution and those interested may obtain a copy by addressing a request to the Bureau.

Note.—Only a limited supply of these publications is available for free distribution, and applicants are asked to cooperate in insuring an equitable distribution by selecting publications that are of special interest. Requests for all papers can not be granted. Publications should be ordered by number and title. Applications should be addressed to the Director of the Bureau of Mines, Washington, D. C.

New Publications Acknowledged.

"American Lubricants" (From the Standpoint of the Consumer), by L. B. Lockhart, consulting and analytical chemist. 225 pages and index. Illustrations from photographs and drawings. Easton, Pa., The Chemical Publishing Co. London, Williams & Norgate. Tokio, Maruzen Co., Ltd.

"Chemical French," an Introduction to the Study of French Chemical Literature, by Maurice L. Dolt, Ph.D., Professor of Chemistry, North Dakota Agricultural College. 398 pages. Easton, Pa., The Chemical Publishing Co. London, Williams & Norgate. Tokio, Maruzen Co., Ltd.

Pratt Co. Moves New York Office.

Pratt Engineering & Machine Co., manufacturers of equipment for sulphuric acid works, acid pumping apparatus, etc., with main offices and works at Atlanta, Ga., have moved their New York office from 61 Broadway to 25 West 44th street, that city. Joel Hurt is president of the company, George F. Hurt, treasurer, and C. A. Murphy is sales manager of the New York office.

All-State Chemical Mfg. Co.

With a nominal capital of $5,000, the All-State Chemical Manufacturing Co. has been incorporated in New York to engage in the manufacture of chemical and allied products. The incorporators are W. Graveur, D. E. Hubener and F. J. Nice, 525 W. 169th St., New York City

ULTRA VIOLET LIGHT

(*Concluded from page* 150.)

1.31; violet light (methyl violet solution screen), 1.21; and ultra violet light (mercury vapor lamp with nitrosodimethylaniline solution screen), 1.17.

Effect of Ultra Violet Rays on Rainfall.

A theory has been advanced that ultra violet rays form nuclei which causes the variation in rainfall at various localities during the different seasons. *Schultz* (Nature, London, 1912, 68) has made a great many determinations of the ultra violet content of light reaching the earth, and has not been able to find any relation between this content and the rainfall.

(To be continued in the March number.)

INORGANIC CHEMICAL SYNONYMS

(*Concluded from page* 152.)

Bismuthyl Chloride
Oxychloride of Bismuth
Bismouthous Chloride
Cosmetic Bismuth
Basic Bismuth Nitrate 304.03
Bismuthi Oxynitras
Bismuthi Subnitras
Bismuthum Album
Calx Vismuthi
Oxynitrate of Bismuth
Bismuthyl Nitrate
Basic Nitrate of Bismuth
Pearl White
Flake White
Spanish White
Paint White
Bismuth White
Bismuth Trioxide 464
Bismuthi Trioxidum
Bismuthous Oxide
Teroxide of Bismuth
Protoxide of Bismuth
Bismuth Yellow

Strauss & Buegeleisen Move.

Strauss & Buegeleisen, manufacturers and dealers in safety goggles for use in the chemical and allied industries, have entered their new quarters at 438 Broadway, New York.

H. Reeve Angel Co. in New Home.

H. Reeve Angel & Co., distributors for Whatman Filter Papers, have moved their offices and stockrooms from 120 Liberty street to 9 Spruce street, New York, where they will have larger quarters and better marketing facilities.

Atlas Color Works Opens New Plants.

Announcement has been made by the Atlas Color Works, Inc., Brooklyn, N. Y., that the capital stock of the concern has recently been increased from $25,000 to $100,000, due to the expansion of their business. The firm has opened two new plants for the manufacture of indigotin, alizarin and sulphur colors.

FOREIGN TRADE OPPORTUNITIES

These Opportunities for Foreign Business Relations Are Made Public by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce, Washington, D. C. Names, Addresses and Details May Be Obtained from the Bureau or Any of Its Branches. Refer to the Number of Each Opportunity and Place Inquiries for More Than One on Separate Sheets.

Cellulose Acetate.

26200—A man in England is in the market for large quantities of cellulose acetate.

Celluloid.

26202—A man in England desires to purchase clear sheets of noninflammable celluloid.

Drugs and Chemicals.

26160—An agency is desired by a company in Peru for the sale of drugs, chemicals, canned goods, provisions, general merchandise, dry goods, etc. Correspondence may be in English. References.

Caustic Soda, Soda Ash, Acetic Acid.

25613.—An agency is desired by a firm in Brazil for the sale of industrial chemicals, caustic soda, soda ash, acetic acid suitable for the textile and soap industries, and all kinds of dyes suitable for cotton textile industry. All business is desired on a commission basis. Cash will be paid. Shipments are preferred through some reputable export house which understands documentation for Brazil, Correspondence may be in English. Reference.

Indigo, Carmine and Coal-Tar Dyes.

25916—An agency is desired by a company in Chosen for the sale of yellow, black, green, pink, and red indigo, carmine, and coal-tar dyes. Goods are desired on consignment, to be paid for or returned within a specified time. Goods should be put up in 1-pound tins, about 100 tins to the case. Correspondence may be in English. Samples and prices should be submitted. References.

Caustic Soda, Tar, Chemicals.

26259—A man in Brazil desires to represent American manufacturers and exporters of wheat, flour, condensed milk, codfish, fresh and preserved fruits, china and enameled ware, household utensils, hardware, iron tools, axes, knives, cutlery, brassware, cement, ship pitch and tar, caustic soda, tin plate, sporting goods, furniture, typewriters, adding machines, all kinds of paper, harmonicas, toys and trinkets, watches, boots and shoes, dressed hides, drugs, chemicals, pharmaceutical products, pneumatic instruments, textiles, hosiery, shirts, and novelties. References.

Fertilizers.

26510.—An agency is desired by a man in Algeria for the sale of agricultural implements, household articles, tinware, binding twine, fertilizers, coffee, tea and canned goods. He also wishes to make direct purchases. Payment will be made by cash against documents in New York or at destination. Correspondence should be in French. Reference.

Bituminous Paints; Waterproofing.

26509.—An official connected with office of the civil commissioner of a city in Mesopotamia is desirous of securing the latest catalogues and price lists of agricultural machinery, graders, ditchers, excavators, machine tools, motor engines, bituminous paints, waterproofing, concrete machinery and material for reinforced concrete.

Orthotoluol Sulphamid.

26114—The representative of a manufacturers' association in South Africa who will be in the United States for a period of three months desires to establish permanent connections with American firms in a position to furnish monthly 3 hundredweight of orthotoluol sulphamid to be used in the manufacture of saccharin. He also wishes to purchase woodworking machinery, foundry equipment, molding machines, envelope machinery, air compressors, marine motors, machinery for producing caustic soda from salt, and machinery for making calcium carbide, also orthotoluol sulphamid. Further information may be had on application to the Bureau or its district offices. References.

Aniline Dyes, Chemicals, Dynamite.

26273—A man in Brazil wishes to buy aniline dyes, chemical products, hardware, cement in barrels, tin sheets in boxes, steel beams, dynamite, barbed wire, smooth wire, steel wire cables, iron bars and plates, copper plates and wire, brass plates and wire, zinc corrugated tiles, linseed oil, zinc white, turpentine, shovels and picks, tar, iron beams, round brass and copper bars, lead and zinc bars, tin rods, potash, steel for springs, steel for making tools, caustic soda, carbonate of soda, chloride of lime, and soda sulphuret. Quotations may be made f. o. b. New York. Payment will be made against documents or by opening credit with local bank. Correspondence may be in English. References.

DISTILLATES

News Notes of Chemical and Allied Industries

Providence Dye Works Burns.

A portion of the plant of the Providence Dye Works, Providence, R. I., was recently destroyed by fire with an estimated loss of $35,000.

Oil Products Plant Burns.

With a loss estimated at $20,000 fire recently destroyed a portion of the plant of the Townsend Oil Products Co., Lima, Ohio.

New Wood Distillation Plant.

At a cost of $700,000 the Kingsport Wood, Reduction Co., will erect a large plant at Kingsport, Tenn., for the manufacture of wood distillates.

To Rebuild Burned Phosphate Plant.

Work will be started immediately by the International Agricultural Corp. to rebuild its phosphate plant at Mt. Pleasant, Tenn., which was recently destroyed with a loss of about $15,000.

New Government Acetone Plant.

A new Government plant will be constructed at Collinwood, Tenn., by the Tennessee Iron & Railroad Co. at a cost of about $800,000. The acetic acid and acetone will be utilized by the Government, while the by-product charcoal will be used for fuel in the iron furnace which the corporation is now building.

Acetone for Aeroplane Wings.

Acetone, which is used to mix with varnish for coating aeroplane wings, will be produced at the new chemical plant which the U. S. Government is planning to erect at Mechanicsville, N. Y. This plant will utilize by-products from the plants of the West Virginia Pulp & Paper Co.

Kalbfleisch to Rebuild Burned Plant.

Operations will be begun at once to replace that portion of the plant of the Kalbfleisch Chemical Co., 3rd Ave. & Baltic St., Elizabeth, N. J., which was recently destroyed by fire.

Will Make Cartridges.

The Burns Cartridge Manufacturing Corp. have been incorporated under the laws of Delaware with a capital of $500,000 to manufacture cartridges, etc.

New Plant for Norcross Chemical Co.

Acids, chemicals and munitions will be manufactured in a new plant to be constructed at once by Norcross Chemical Co., to be located near Stone City, Colo. The buildings will include tank houses, acid towers and boiler rooms.

Merrimac Chemical Co. to Rebuild.

The damaged section of the plant of the Merrimac Chemical Co., Woburn, Mass., which was recently destroyed by fire with an estimated loss of about $10,000, will be immediately rebuilt by the company.

Heller & Merz to Operate in New York.

Authorization papers to operate in New York have been filed by the Heller & Merz Co., Newark, N. J., manufacturers of chemicals, dyes etc. The capital is $500,000 and P. Schnorrenberger, 503 Hudson St., has been appointed New York representative.

To Recover Toluol from Illuminating Gas.

Machinery for the recovery of toluol will be installed by the Springfield Gas Light Co., Springfield, Mass. The company expects in this way to recover about 30,000 gallons annually for government use in producing T. N. T.

New Kelp Reduction Plant.

Plans are being made for the establishment of a large new plant at Oakland, Cal., by the Occidental Chemical Co., which is a reorganization of the kelp reduction interests of the California Chemical Co.

Paints, Varnishes, Etc.

With a capital of $50,000, the Merrimac Veneer Company has been incorporated at Byram, Mississippi, to manufacture paints, varnishes, etc. The incorporators are Frank Morrison, Robert Morrison and Thomas McCase.

Dyestuffs and Allied Products.

The Eureka Aniline Products Corporation, New York, has been incorporated with a capital of $10,000 to manufacture dyestuffs and allied products. The incorporators are H. H. Suhr, H. P. Velte and R. Bennett, 503 West 169th Street.

Heller & Merz Incorporated.

The Heller & Merz Company, Newark, N. J., has recently been incorporated with a capital of $1,500,000 to engage in the manufacture of chemicals, dyes and allied products. The incorporators consist of A. Foshay, A. G. Thanum, and Arthur Williams, all of New York.

Chemicals and Allied Products.

Blackman & Fink, New York, have been incorporated with capital of $25,000 to engage in the manufacture of chemicals and allied products. The incorporators are M. Fink, and J. and E. Blackman, 66 East 99th Street.

U.S. Acid Proof Paint

SEND FOR SAMPLE ON TIN—READY TO TEST

This paint is proof against the most destructive acids and alkalis, or fumes of the same, in any strength, even to chlorine. It is also proof against steam conditions and dampness.

U. S. ACID PROOF PAINT contains no oil, asphalt, coal tar or pigment. It air dries in about 30 minutes and is permanently flexible. It will adhere to any surface, will not dry out, crumble or peel, and is non-deteriorating even when subjected to the most severe conditions. It is a deep black, will stand dry heat to 350 degrees Fahr. and is highly electrolysis proof.

Compulsory Syndicates in Germany.

The German Government is developing a pronounced policy in favor of compulsory syndicates of the great industries, more especially in connection with the purchase of materials from other countries. The purpose is to avoid the results of competition, after the war, in securing the necessary raw materials for resuming manufacture on a large scale, and to strengthen individual industries for meeting foreign rivalry in the most effective manner.

No effort has yet been made to force this policy upon the chemical industry, but the matter is under discussion.

At the recent annual meeting in Berlin of the Society for the Protection of the Interests of the Chemical Industry the topic came under discussion. Much opposition was evident to any plan involving State control. It was claimed that the industry demanded the restoration to the fullest extent of freedom in trading, and that the individual corporations should continue, as in the past, to be considered as members of the creative class, able to act independently in their activity for the nation's welfare.

There is evidently much chafing under the manifold restrictions placed upon industrial freedom in Germany during the war, and a desire to prevent any continuance of the policy during peace. The dyestuff industry has already voluntarily consolidated the various factors to such an extent that it can practically act as a unit in selling or purchasing abroad. What it objects to is any material degree of control, on the part of government officials, in formulating and carrying out its plans. There is no opposition to a general supervision of the activity of syndicated industries.

There is no doubt but that the German color industry will leave no stone unturned to recover every possible fraction of its former dominating position in this and nearly every other country. It is abundantly able to carry on its campaign without governmental assistance. The question may, however, be fairly posed, whether it would not be to the advantage of our American color industry, and also of the corresponding industries in Great Britain, France and Japan, if a similar unification of interests should not be adopted by those who will soon be called upon to defend themselves against bold and determined efforts to wreck the results of the past three years.

ENZYMES

Their Chemical Composition, Mode of Action, Basic Ingredient and Synthetic Preparation

with

Note on Hemicellutase

By

CHARLES B. DAVIS, F. C. S.

Modern text books and chemical literature in general inform us that enzymes cannot be produced by chemical means and are of unknown chemical composition. For example:—

Euler-Pope (*General Chemistry of the Enzymes. Page* 7, 1912.)

> "The dynamics of the enzymes suffers in considerable measure from the disadvantage that we know nothing of the composition of these bodies, and hence can form beforehand no idea of the chemical processes taking place during their action."

Cohenheim (*Enzymes.*)

> *Page* 1. "Chemistry cannot produce enzymes."
>
> *Page* 22. "We cannot detect or estimate the enzymes themselves. We can only observe their action."

Sykes. (*Brewing, Page* 109, 1897.)

> "Conclusions as to the nature of diastase are all merely suppositions, with no direct evidences."

Holleman-Walker. (*Organic Chemistry.* 1915, *Page* 286.)

> "The chemical structure of the enzymes is at present wholly unknown. Most of them have not been obtained in the pure state. Their power of decomposing compounds is also not understood. Hitherto, only small insight has been obtained into the conditions upon which their action depends."

Effromt-Prescott. (*Biochemical Catalysto in Life and Industry.* 1917, *Page* 16.)

> "Mechanism of action of enzymes—We may now inquire how enzymes effect these results. It is not easy to answer this question, since the nature of these bodies is unknown."

Similar statements are to be found throughout scientific journals and works on chemistry so it is not unreasonable to say that, previous to the publication of this paper, nothing but the action of these bodies was known.

This paper deals with their synthetic production by chemical means, including their chemical composition, and why they act and how they act on carbohydrates, albumin, sugar, etc. It is also shown why acids, alkalies, metals and certain elevated temperatures cause them to become inactive.

The writer has hesitated for some little time to publish this article on account of the manner in which chemical research is received. The attitude of scientists toward this class of work is not encouraging, to say the least.

Let us take, for instance, the case of E. Buchner, who, in the *Berichte der Deutschen Chemischen Gesellschaft,* No. 30, 1897, pages 117-121, published his preliminary researches on a newly discovered enzyme of fermentation, called by him "Zymase." In the same paper, No. 30 and 31, he published further researches on the same subject.

In the issue No. 31 no less than three chemists denied the existence of such an enzyme and of the phenomena he described.

In the face of all this, the existence of the enzyme is now a proven fact.

It would serve no good purpose to further expand this paper by citing additional instances of premature criticism; the above is sufficiently representative to illustrate the experiences of many. Yet, even at the risk of including matter which does not properly belong in a paper of this sort, the impulse to refer briefly to the writer's own case is strong. It must be kept clearly in mind, however, that honest criticism is resented by no right-thinking individual, no matter what his particular line of endeavor may be. But a certain form of criticism—that which hastily assails results without being in its own turn based upon the results of painstaking, adequate tests—is encountered with lamentable frequency in chemical literature. And if the foregoing homily, and what follows hereafter, should serve to lessen in the slightest degree this most useless of in-door sports it is believed that its intrusion has not been altogether unwarranted.

After the publication of the writer's paper on "A Starch-Forming Enzyme," which appeared in the Journal of Industrial and Engineering Chemistry, February, 1915, several well-known chemists went on record to the effect that they could not confirm the results given, some of their criticisms being:—

1. "Not the slightest indication of the activity of

New York, October 25th, 1917.

State of New York.
ss:
County of New York.

I, Ludwig Saarbach, Ph. D., of 114 Pearl Street, New York City, a chemist and graduate of Leipzig University of Germany, do solemnly swear that I am in no way interested in the matter contained herein, except in making the tests or experiments below described.

I do further solemnly swear that the results obtained by me with malt extract and corn starch hereinafter set forth are true to the best of my knowledge and belief.

Ludwig Saarbach.

Sworn to before me this 25th day of October, 1917.

L. F. Froelich

New York, October 25th, 1917.

Mr. Charles B. Davis,
469 West 152d Street,
New York City.

Dear Sir:—

At your request I obtained some malt and corn grits # and made a number of experiments with the view of investigating the statement, that an extract of malt contains besides the enzyme "DIASTASE" another enzyme, which under proper conditions forms anew bodies giving the starch-reaction, after all starch originally present had been converted by the diastase of the malt. For this purpose I made

(A) Malt extract, using 1 part of malt to 3 parts of water and filtering after standing for 4 hours.

(B) A portion of this solution A. was immersed into a cold water bath, which then was heated up to 75 °C. and held at this temperature for 5 minutes. The solution was then cooled and filtered.

(C) A 4% starch paste from corngrits by heating to 90 °C.

Experiment 1.

Equal parts of starch-paste C. and filtered solution B. were heated on the boiling waterbath and the mixture frequently tested with Iodine, until no further color-reaction

C.B.D. 2. October 25th. 1917.

was obtained. The solution, after reaching 82 - 83 °C. was quickly cooled and gave then on testing with Iodine again a strong blue color. This indicates the presence or rather the formation of a substance, which gives the starch reaction, after all starch originally present has been converted and hydrolized. On addition of a portion of solution A., containing fresh diastase, and heating to about 60 °C. the iodine reaction very soon disappeared, which fact also points to the presence of a substance of the properties of starch.

Experiment 2.

A mixture of equal parts of
Maltsolution A. and
Starchpaste C.

was slowly heated up to 68 °C. until the starch had been converted. A portion of this mixture was then rapidly cooled in ice and showed then again a strong blue iodine reaction; another portion was permitted to cool slowly, when no color was obtained on addition of Iodine, even after cooling down to 4 °C. This experiment indicates, that the statement made by you about the activity of the new enzyme at lower temperatures with the formation of the same starchlike body, is reasonable. In the first case the rapid cooling protects the newly formed starchy substance from the action of diastase still present, which will attack it on slow cooling.

C.B.D. 3. October 25th, 1917.

From the results obtained by me, as described above, the conclusion may be drawn that this action of generating a starchlike body can not be ascribed to the activity of Diastase, but to a different enzyme, which attacks other constituents of grains, like the cell-walls.

Very truly yours

Ludwig Saarbach
Ph. D.

Brewers' refined grits.

a Starch-Forming enzyme was discovered."

2. "The pretended Hemicellutase, etc. Not the slightest indication of its existence."

3. "In my opinion the entire article is erroneous."

This person went so far as to say that "if an enzyme has an optimum temperature of 82.5° C. we certainly should not expect that a mere subdivision of the substrate should reduce its optimum temperature over 60° C., that is, from 82.5 to 10-20° C."

He did not appear to know that diastase acts on gelatinized starch at an optimum of 60° C., while if the starch (substrate) be subdivided as in soluble starch the conversion will take place at 20° C., as in the Lintner method.

These are samples of the criticisms with which one has occasionally to deal. Yet here is one which gives some hope:—

4. "An enzyme which transforms hemicelluloses into starch appears to be a theoretical impossibility from a physiological standpoint, as it would have to effect changes which can only be attributed to the living cell."

This last admission, coupled with the fact that the starch-forming enzyme in question has been proven to exist (see affidavit), formed the basis and desire for the writer's research into enzymatic action and the chemical production of enzymes.

As before stated, such criticisms can be found throughout chemical literature. There has only to appear an article describing something new and the following is very likely to appear at the end of an abstract:

> Note—No experimental evidence is given in this paper justifying the author's claims, etc.—*Editor.*

Thus others who desire to rush into print are offered an excellent opportunity to follow with similar denunciations.

Arrhenius, in 1887, met with great opposition when he presented his doctrine of electrolytic dissociation.

Lately a disinterested party has confirmed the existence of Hemicellutase, and his affidavit, together with his results, is reproduced on page 165.

Although it was stated in the writer's former paper that Hemicellutase was capable of effecting the saccharification of raw cereals without boiling, yet after the republication of this article in *"Letters on Brewing,"* April, 1915 (a publication of Hantke's Brewing School) the writer was dumfounded to see a paper appear in the *"Communications of the Masters Brewers' Association of the United States"* for April, 1917, entitled "The Saccharification of Raw Cereal Mashes," in which the author attempted to take the credit of being the first to convert such raw cereals without boiling. The author of the above mentioned paper was one of the faculty of Hantke's School!

Good honest criticism should be and is welcomed at all times, but it should be backed by intelligent experiments and not by the unsupported opinion of those who, having attained some prominence in their chosen profession, believe that there is nothing new under the sun.

Author's Note on Hemicellutase.

Hemicellutase is more active at lower temperature than diastase; therefore starch is formed all the while the diastase is converting it (*Figs.* 1 *to* 6). But less starch is formed than the amounts converted; therefore, on cooling the mixture, the diastase becomes inactive, while the hemicellutase continues to form starch, and we again obtain the deep blue reaction with iodine. This color reaction is shown in *Fig. 7* of colored chart on insert. *Figs* 1, 2, 3 *and* 4 show the gradual disappearance of starch, while *Fig.* 5 is the dextrin reaction, and *Fig.* 6 the point where the diastase is just converting the starch formed by hemicellutase.

One should be careful not to heat the mixture of gelatinous and finely divided hemicelluloses too long after the disappearance of a starch reaction, for fear of converting them to sugar.

With vitrified cells, as in cracked corn, rice, and malt mashes, a temperature of 82.5° C. (optimum for this type of cell wall) is best suited for the transformation to starch. Just as diastase can convert to sugar soluble starch at 20° C. and gelatinous starch at 60° C.; so, too, can hemicellutase form starch between 10-90° C., according to the state of vitrification.

Fig. 15 shows the partial conversion of the cell wall to starch by the enzyme Hemicellutase.

Enzymes by Chemical Synthesis.

As a starting point for the chemical formation of enzymes, the writer has selected fresh egg albumin, since it contains the salts of potash, soda and calcium, so necessary for the formation of the co-enzymes, and traces of metallic salts, and also since it is easily obtainable, although other types of albuminous bodies, from wheat, barley, corn, milk, etc., may be employed.

Even egg albumin contains but small amounts of the selective nitrogeneous matter capable of forming enzymes.

In order to forestall arguments based on the ground that egg albumin, as the writer has used it, contains enzymes or co-enzymes in itself, he boiled the albumin and took the uncoagulated portion, precipitated it with alcohol, dissolved it in water, boiled the resulting solution again and then produced enzymes of high activity by the methods hereinafter described. All final tests were carried out in the presence of such antiseptics as toluene and chloroform to prevent any growths from mold and bacteria.

The resulting enzymotic products were highly phosphorescent in extremely dilute solutions, gave no reaction for albumin, but decided reactions for peptone, and possessed all the essential properties of enzymes as follows:—

1. Some soluble, others insoluble, in water.
2. Large quantities of substrate were acted upon with minute amounts of the enzymotic product,

and with very little weakening of the enzyme itself.

3. Active at very low temperatures, increasing in activity with rise of temperature and destroyed at elevated degrees approaching 100° C.
4. Precipitated by alcohol and salts.
5. Fix themselves to various substances by adsorption.
6. Sensitive to metals, acids and alkalies.
7. Resistant to antiseptics.
8. Some partly removed by dialysis, or porous filter.
9. Colloidal, and act as electrolytes or salts.
10. Affected by products of change.

The writer wishes to state before proceeding that mixtures of enzymes and co-enzymes are composed of a phosphorus anhydride which is the "KEY" described hereafter, and for which he suggests the name "Vitazymae," and a protective colloid combined with traces of magnetic metallic albuminois, and salts of potash, soda and calcium.

In all tests the writer has used a mixture of phosphorous and hypo-phosphorous acids as a source of anhydrid, and fresh egg albumin for the protective colloid.

EXPERIMENTAL.

Table I.

Tests with Alkaline, Neutral and Saturated* Albumin.

*As used above, "saturated" is when the albumin contains just sufficient mixed acids to reduce a solution of copper sulphate containing some soluble starch.

Solutions used:

(1) 0.014% soluble starch.
(2) 1 to 100 of 50% mixed acids.
(3) 10% albumin, alkaline, neutral and saturated.

(1)	(3) Normal Alkaline.	(3) 11.1% (2) Neutral.	(3) 50.3% (2) Saturated.
5 cc.	0.25 cc.	0.25 cc.	0.25 cc.
5 cc.	0.50 cc.	0.50 cc.	0.55 cc.
5 cc.	1.00 cc.	1.00 cc.	1.00 cc.
5 cc.	2.00 cc.	2.00 cc.	†
5 cc.	3.00 cc.	†	2.00 cc.
5 cc.	†	3.00 cc.	3.00 cc.
5 cc.	4.00 cc.	4.00 cc.	4.00 cc
5 cc.	5.00 cc.	5.00 cc.	5.00 cc.

†Indicates point of complete conversion of starch to sugar and dextrin at 70 F. after one hour by the following number of cc. of (3):

Alkaline	3.75 cc.
Neutral	2.75 cc.
Saturated	1.45 cc.

Notes: Iodine reactions immediately after mixing were as follows:

Alkaline	All Blue
Neutral	All Blue
Saturated	Blue up to 2.00 cc.

After boiling the Alkaline, Neutral and Saturated solutions of (3) no conversion of starch to sugar was obtained in any set of tests.

(1) and (2) mixed in varying proportions have no effect on the starch.

(2) is not affected by heating to elevated temperatures alone.

The amount of (2) required to render the albumin neutral or saturated varies with different eggs. Sugar by Fehling showed 80% maltose and 20% dextrin.

Table II.

Test with Large Amount of Soluble Starch.

Reagents used:

75 cc. of (3)
25 cc. of 0.135% soluble starch
0.56 cc. of 50% mixed acids.

The above was mixed and allowed to stand cold, testing with iodine and Fehling's solution at intervals with the following results:

	Iodine Reaction.	Fehling Reduction.
Immediate mixture	Deep blue	None.
After five minutes	Violet	Slight.
After ten minutes	Red violet	Distinct
After fifteen minutes	Red	Decided.
After thirty minutes	None	Heavy.
After sixty minutes	None	Heavy.

Note:—When working with small amounts of soluble starch, one must destroy the mixed enzymes by boiling immediately after the sugar is formed, otherwise the sugar splitting enzyme present will convert it to alcohol and carbonic acid and the resulting liquid will show very little or no reduction by Fehling solution.

The results obtained in *Table I* above show the presence of various enzymes, and it is the writer's purpose to show that the difference in quantity of albumin required for conversion between the "saturated" and the "neutral" is due to an enzyme similar to diastase.

The results from the alkaline, neutral and saturated egg albumin show conclusively that the enzyme preparation consists of a mixture of these bodies. This is further shown by the fact that it is capable of producing at least maltose, dextrin, peptone and alcohol.

By taking the difference between the neutral and the saturated egg albumin results (*Table I*) as due to diastase, we obtain figures as follows:

2.75 — 1.45 = 1.30 cc. of saturated egg albumin necessary to convert 0.0005 gr. soluble starch to maltose.

1.30 cc. of saturated egg albumin contains 0.065 gr. albumin, and this albumin contains 0.0000041% of diastase.

$0.065 \times 0.0000041 = 0.000000266$ gr. "Diastase," to convert 0.0005 gr. soluble starch to maltose.

$$\left.\begin{array}{lcl} 0.000000266 & & 0.0000180 \text{ “Diastase”} \\ & \text{or} & \\ 0.000500000 & & 0.0337500 \text{ Starch.*} \\ & & 0.0050000 \text{ Malt.*} \end{array}\right\} = 27{,}777. \text{ diastatic power.}$$

*When 0.03375 gr. soluble starch is converted to maltose by 0.005 gr. malt, at 70° F. after one hour, it is taken to equal 100° Lintner.

This agrees very closely with the calculated 26,595. below.

One part of this enzyme, therefore, converts 1,877 times its weight of starch into maltose, after one hour at 70° F., as against 6.75 for malt. Malt of 100° Lintner, therefore, contains only 0.0013% pure diastase. This is, no doubt, why it was never separated from malt in a pure state.

In the reactions showing the conversion of starch and water to sugar and dextrin (See Fig. 14), the molecular weight of soluble starch is taken as 32,400. The molecular weight of water is taken as 18.

It is only the loosely combined water of the "KEY" (*see Fig.* 8) that enters into combination with the starch. This the writer has found to be the case from the chemical reactions of the enzyme mixture at various times during the conversion of the starch.

Therefore, 32,400. is to 18 as 0.03375 gr. starch is to x or 0.0000188 gr. water entering into combination with the starch at each cycle of the "KEY."

$$\left.\begin{array}{ll}0.0000188 & \text{Water or enzyme}\\ 0.0337500 & \text{Starch}\\ 0.005000 & \text{Malt}\end{array}\right\} = 26{,}595 \text{ diastatic power.}$$

PREPARATION OF THE ENZYME.

Ten thousand grams of egg albumin (whites from about 30 dozen eggs) was treated with an equal volume of cold water and agitated until completely disintegrated.

This was filtered through cotton and the precipitate washed with cold water.

To this was added 1000 cc. of the 50% mixed acids, 100 grams sodium acetate, and a saturated solution of picric acid.

The voluminous precipitate of proteins was removed by filtration and the precipitate again washed with a saturated picric acid solution.

Filtrate and washings were evaporated to 500 cc. and 95% alcohol and ether added until a precipitate was obtained.

After standing two days in the cold, this precipitate was collected and washed with alcohol and ether until the filtrate was free from picric acid. After dissolving in cold water and evaporating over calcium chloride, the precipitate gave a residue of the mixed enzymes of 0.0013 gr. or 0.000013%.

This residue of mixed enzymes (*See Fig.* 9) was extremely iridescent and gave off the characteristic odor of albumin on ignition.

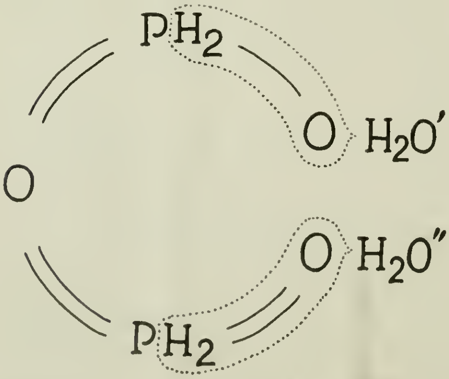

Fig. 8—Cycle or "KEY" of all enzymatic action illustrated graphically ("Vitazymae").

A portion gave an alkaline ash, showing absence of a nucleo albumin.

A water solution was highly fluorescent and phosphorescent, and traces were capable of immediately converting starch into sugar and dextrine, and finally into alcohol and carbonic acid gas.

The water solution, when filtered through parchment paper, resulted in a filtrate which had no activity, and a residue which had lost most of its activity.

On re-mixing, however, this became extremely active and similar to the original mixed enzymes.

Minute amounts, added to a dough consisting of wheat flour and water, and baked after the manner customary in making bread, resulted in a decidedly aerated loaf, as compared to one prepared with water alone. (*See Figs.* 10 *and* 11.)

The mixed enzymes, the separated enzyme and the co-enzyme are shown in the accompanying microphotographs, for the making of which the writer is indebted to Dr. James H. Stebbins.

The enzyme mixture is semi-crystalline. (*Fig.* 9.)

The co-enzyme is almost wholly crystalline. (*Fig.* 12.)

The enzyme "diatase" was chiefly amorphous (*Fig.* 13). The play of colors may be seen in the rings A A.

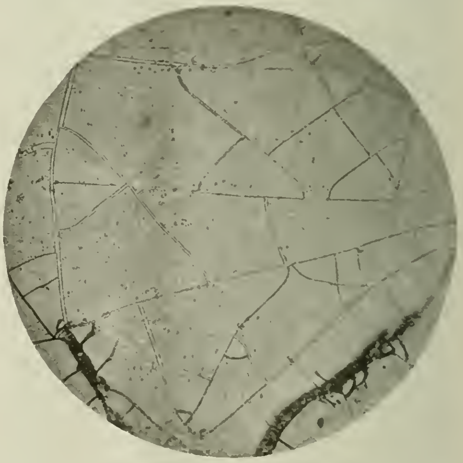

Fig. 9—Microphotograph of residue of mixed enzymes, from which Figs. 12 and 13 were obtained (100 diameters).

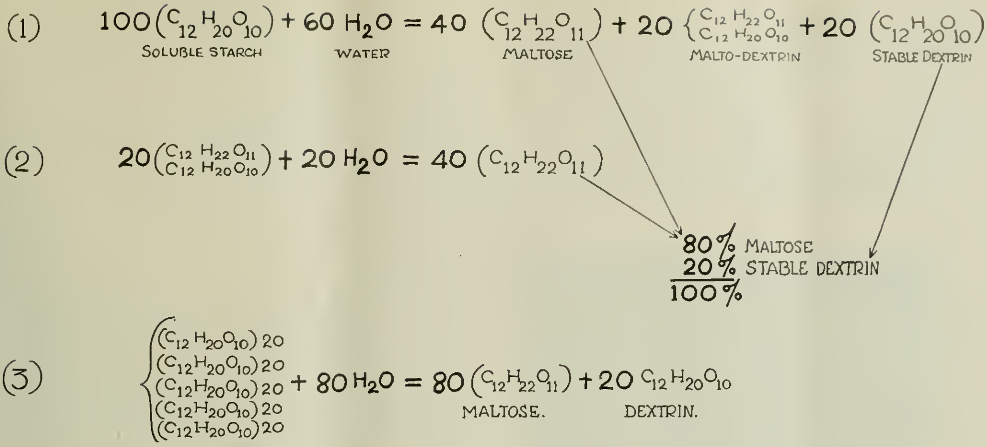
A minute quantity of the mixed enzymes added to some sterilized malt wort and warmed to about 20° C. immediately caused a generation of carbonic acid gas which increased to foaming within five minutes.

This mixture on distillation under a reflux condenser showed unmistakable presence of ethyl alcohol, by the usual chemical tests.

Roses, decolorized permanently with sulphurous acid, washed free of acid and the last traces destroyed with hydrogen peroxide, were immediately restored to their original glory of both color and fragrance by small quantities of the mixed acids, sufficient to form enzymes within the petals. The coloring may be extracted from leaves and flowers by this method.

Green fruit immersed in a 1 to 200 dilution of the mixed acids ripens very quickly from the same formation of enzymes in a high state of activity.



$$(1)\quad 100\underset{\text{Soluble starch}}{(C_{12}H_{20}O_{10})} + 60\underset{\text{Water}}{H_2O} = 40\underset{\text{Maltose}}{(C_{12}H_{22}O_{11})} + 20\underset{\text{Malto-dextrin}}{\left\{\begin{matrix}C_{12}H_{22}O_{11}\\ C_{12}H_{20}O_{10}\end{matrix}\right.} + 20\underset{\text{Stable Dextrin}}{(C_{12}H_{20}O_{10})}$$

$$(2)\quad 20\begin{pmatrix}C_{12}H_{22}O_{11}\\ C_{12}H_{20}O_{10}\end{pmatrix} + 20\,H_2O = 40\,(C_{12}H_{22}O_{11})$$

$$(3)\quad \left\{\begin{matrix}(C_{12}H_{20}O_{10})\,20\\ (C_{12}H_{20}O_{10})\,20\\ (C_{12}H_{20}O_{10})\,20\\ (C_{12}H_{20}O_{10})\,20\\ (C_{12}H_{20}O_{10})\,20\end{matrix}\right. + 80\,H_2O = 80\underset{\text{Maltose.}}{(C_{12}H_{22}O_{11})} + 20\underset{\text{Dextrin.}}{C_{12}H_{20}O_{10}}$$

Fig. 14—Equations showing steps in the hydrolysis of starch to maltose and dextrin.

PREPARATION AND SEPARATION OF THE SYNTHETIC "DIASTASE"

Ten thousand grams of egg albumin (whites from about 30 dozen eggs) was treated with an equal volume of cold water and agitated until completely disintegrated. This was filtered through cotton and the precipitate washed with cold water.

Filtrate and washings were treated with 225 cc, of 50% mixed acids (sufficient to just neutralize), which caused a precipitate to tumble out of solution.

This precipitate was separated by filtration and washed until free from albumin and peptone. This was indicated when Tanret's reagent gave no reaction. The precipitate was then dissolved off the filter with excess of the mixed acids (more than sufficient to "saturate"). The filtrate, measuring 100 cc., was then treated with a saturated solution of picric acid and the precipitate removed by filtration. The filtrate and washings, measuring 200 cc., were treated with 200 cc. absolute alcohol and 300 cc. absolute ether.

No precipitate was visible until after a lapse of two days. After four days in the cold, the deposit of "diastase" was collected, washed with a mixture of alcohol and ether, and dissolved off the filter and evaporated over calcium chloride.

The residue weighed 0.00041 gr., the equivalent of 0.0000041% "diastase."

This "diastase" (*Fig.* 13) was extremely active on soluble starch in the cold, converting 0.03375 gr. to sugar in one hour at 70° F. with 5 cc. of its 1% solution. This proves the correctness of the "KEY," and also that an excess of protein, as present in eggs or malted cereals, is without effect on its action.

These reactions tend to point to the formation of enzymes in plant and animal life, through the presence of these mixed acids secreted during germination or growth.

By following the above method, as for "diastase," and salting out the slightly acid egg albumin with sodium sulphate at 90° F., a product is obtained having properties similar to pepsin.

The type of albumin in eggs, which goes to form these enzymotic bodies, is a phosphorized mucoid or a nucleoized glycoprotein, carrying its phosphorus as an anhydrid. Only minute quantities are required to act as the protective colloid.

Egg albumin contains but minute quantities of this selective mucoid capable of carrying the phosphorus anhydrid, and although the "KEY" to the enzymes is dependent wholly on its anhydrid, still the mucoid is absolutely required as its protective colloid.

This phosphorus constituent of the "KEY" is in most cases undetectable, but in other cases, as in samples of the writer's preparation about three years' old, the anhydrid is gradually changed into a detectable form.

Fats, Salts and Carbohydrates of many types, when mixed with the acids, fail to produce active bodies, as it is absolutely necessary to add the above-mentioned albuminous matter to obtain an enzymotic action. This goes to prove that nitrogen is essential to the production of enzymes.

"KEY"	+	**Substrate**	=	**Product**
to the enzymes (Vita-zymae)		Starch		Maltose & Dedtrin.
		Sugar		Alcohol & CO_2.
		Protein		Peptones.

CHEMICAL ACTION OF THE "KEY" (Vita-zymae)

The half-bound molecule of water is active up to the temperature of destruction of its protective colloid. During the range of activity the water is split off and immediately combines with the substrate (1).

The unsaturated anhydrid again absorbs its lost water and thus forms the cycle of the "KEY" (2) which continues until such time as the temperature or other disturbing influence destroys the protective colloid, when the "KEY," or anhydrid, absorbs water, is hydrolyzed to acid (3) and rendered permanently inactive. A very feeble acid reaction appears and a very faint blue coloration is obtained by molybdate reagent, indicating a hypophosphite. Very high temperatures or ignition of the enzyme splits off all three molecules of water, leaving the neutral phosphorus oxid P_2O. See (4).

(1) $H_4P_2O_3 - H_2O = H_2P_2O_2$, the unsaturated and unstable compound, and this compound plus water:

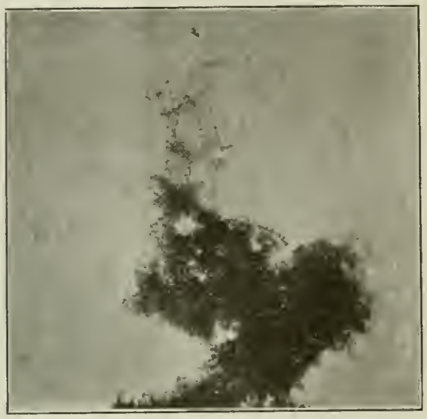

Fig. 15—Showing partial conversion of the cell-walls to starch by the enzyme Hemicellutase.

(2) $H_2P_2O_2 + H_2O = H_4P_2O_3$, thus completing the cycle of the "KEY."

(3) $H_4P_2O_3 + H_2O = 2H_3PO_2$, and

(4) $2H_3PO_2 - 3H_2O = P_2O$, which is incapable of further absorption with water.

At times, especially when sugar is being fermented to alcohol, the writer has found traces of hydrogen phosphide and liquid hydride (PH_3 and P_2H_4), which accounts for the destruction of some enzymes under the influence of sunlight.

FORMATION OF ALCOHOL BY SYNTHETIC ENZYME.

0.0015 gr. of the mixed enzymes introduced into a sterilized solution containing in part 8.5% maltose, 0.12% acidity, 0.20% albumises and proteoses, 0.04% peptones, 0.37% amino compounds and 0.16% phosphated ash, immediately set up a copious generation of CO_2, and on distillation gave an appreciable amount of ethyl alcohol.

Another test with a boiled enzymes solution gave a negative result.

Antiseptics did not retard the reaction.

Slight elevation of temperature, created increased action and foaming.

Unlike yeast of even zymase, the reaction is immediate.

CONCLUSIONS.

An enzyme is only as strong as its protective colloid; when this is destroyed, its anhydrid is split up and the enzyme rendered permanently inactive, unless more anhydrid is added.

The writer has found that the mixed acids are best suited to the synthetic formation of a mixture of enzymes.

The mixture thus formed can be separated by the described methods.

Too much mystery has been connected with enzymes in general.

The anhydrid is devoid of acidity, as are also the enzymes and the oxid (P_2O) formed by the destruction of the protective colloid.

The water is set free "in situ" and immediately combines with the substrate. The reabsorption of water by the "KEY" continues as long as any substrate is present, or until a destructive temperature or agent is introduced for the required period of rest.

This re-constituting of the "KEY" indicates that enzymes are catalytic and contain enormous quantities of available hydrogen ions; also that they do not combine permanently with their substrates.

The enzyme and substrate being in a state of adsorption accounts for the voluminous amount of substrate attacked by minute quantities of enzyme. This is, of course, due to enormous surface action.

The presence of the neutral and insoluble oxid P_2O in the "killed" enzyme explains the reason why Pfeffer could not detect enzymes in the vapor formed by heating them with water.

The continued cycle of the "KEY" proves that there is no chemical relation between the quantity of enzyme and substrate aside from concentration.

The reason why previous attempts to purify enzymes have resulted in weakening their action, is because of the partial destruction of the protective colloid.

All enzymes have the same general chemical composition, their specificity being due simply to the manner of the linking of anhydrid and protective colloid.

Co-enzymes are chiefly crystalline. (*See Fig.* 12.)

Enzymes devoid of co-enzymes are amorphous.

Enzymes exhibit intense iridescence. (*See Fig.* 13, *AA*, showing the play of colors.)

The writer has found that when the enzyme is retarded by the presence of cleavage products, it can be again actuated by precipitating the enzyme and adding fresh anhydrid.

The selective albumin described in this paper is the zymogen, the anhydrid being the activator. Very little of this selective colloid is present in the pure enzyme, it requiring only minute amounts to protect the anhydrid.

Hydrogen peroxide is immediately decomposed by traces of the mixture of enzymes, which indicates a strong catalytic activity.

EDITORIAL COMMENT

German Color Patents

Applications are being regularly filed under the "Trading with the Enemy Act," for licenses to manufacture in this country various chemical products covered by patents issued to German inventors during recent years. One patent out of every 30 granted at Washington is to a German inventor. The proportion among chemical patents is, however, much larger, as one out of every five German patents is of a distinctly chemical nature.

During the decade 1900-1910 the American chemical patents isued to Germans were divided as follows: Alkalies and chlorines, 4; bleaching and disinfecting liquors, 12; chlorates, 1; carbides, 3; carbon dyes, 701; bleaching, 17; dyeing processes, 79; dyes, 10; mercerizing, 10; mordants, 13; mineral acids, 62; fire-extinguishing compounds, 4; metalloids, 14; apparatus, 10; salines, 98; ammonia, 27; soda and potash, 9; carbon compounds, 450; nitro-compounds, 28; hair dyes and tonics, 2; extracts, 18; internal remedies, 52; topical remedies, 20; insecticides, 6; disinfectants, 19.

It will be noted that artificial dyes, dyeing processes, carbon compounds and nitro compounds make up over two-thirds of the total number.

About 10 per cent. of the colors currently in use before the war were under patent protection in 1914. The most important of these colors are in the indanthrene class, the exceedingly fast vat colors, which are so highly valued by cotton manufacturers. Salvarsan and a few other important synthetic medicinals are also under patent protection.

The number of inquiries in regard to the method of securing the permission to manufacture under these German patents has become so large that the Federal Trade Commission has issued the following license rules:

Applicants for a license under patents or copyrights owned or controlled by an enemy or an ally of an enemy are required to file a verified statement with the Federal Trade Commission in concise and non-technical language, covering the following points, stating in each instance the facts upon which any conclusion may be based.

(a) If an individual, that he is a citizen of the United States. If a corporation, that it is organized within the United States.

(b) That the patent or copyright desired to be licensed is owned or controlled by an enemy or an ally of an enemy.

If it is claimed that the patent or copyright is controlled by an enemy or ally of an enemy, the nature and origin of the control should be plainly stated, whether by contract, agency, stock ownership or otherwise.

(c) There shall be attached to the application a Patent Office copy of the patent and a certified abstract of title to it, or a specimen of the copyrighted article and a certified copy of the copyright entries and, in the case of a patent, of a certified copy of the petition and all powers of attorney in the file of the application.

(d) That licensing the applicant is for the public welfare. Specifically, that there is a demand for the patented or copyrighted article or the product of the patented process which is not being met.

(e) That the applicant is able to make or cause to be made the patented or copyrighted article or exercise the patented process. Specifically, that the applicant is technically and otherwise equipped to undertake or procure the manufacture or operate the process and is in fact able to do so.

(f) That the applicant intends to do so in good faith.

(g) The application must be verified by the person applying for the license, and in the case of a corporation by an officer thereof acquainted with the facts recited.

Each application shall be accompanied with a remittance of $100.

A separate application is required for each patent or copyright.

The application should be prepared in duplicate and, for convenience in filing, or good unglazed paper, 8 by 10½ inches, directed to the Federal Trade Commission, Patent, Trade-mark and Copyright Division, and may be transmitted by mail or delivered personally. Personal attendance at the outset is not necessary. If any hearings are desired, notice of them will be given.

In every case where practicable notice of applications for license will be given to the attorney of the patentee or copyright proprietor whose name appears in the file of the application in the Patent Office or the office of the Register of Copyright.

The burden of establishing affirmatively the facts upon which, under the terms of the act, licenses may be granted is placed upon the applicant for license.

Theact provides and the Executive order vests in the Federal Trade Commission the duty of prescribing the conditions of the license.

Only non-exclusive licenses will be issued unless the public interest shall otherwise require.

The act provides (sec. 10 (c)) that licenses shall continue during the terms fixed in the license, or, in the absence of any such limitation, during the term of the patent * * * or copyright registration under which it is granted, and that upon violation by the licensee of any provisions of the act, or the conditions of the license, after due notice and hearing, the license may be canceled.

Licenses for the use of trade-marks, prints and labels will be granted only under exceptional circumstances. Applications for licenses under the following conditions will be entertained:

1. Where the alleged trade-mark is the name of a patented or copyrighted article and a license is granted under the patent or copyright.

2. Where the alleged trade-mark is the name of an article manufactured under an expired patent or copyright.

The act provides that the license fee shall not exceed $100 and not exceeding 1 per cent. of the sum deposited with the alien property custodian. This fund is an amount not to exceed (a) 5 per cent. of the gross sums received by the licensee from the sale of the licensed subject matter, or (b) 5 per cent. of the value of the use of the licensed subject matter as established by the Federal Trade Commission.

The licensee shall file with the Federal Trade Commission semi-annually, on January 1 and July 1 of each year, and oftener if required, a full statement of the extent of the use and enjoyment of the license, and of the prices received from the sale or use of the subject matter of it, and within thirty days thereafter the licensee shall pay to the alien property custodian not to exceed 5 per cent. of the gross sums received from the sale of the licensed subject matter, or if the Federal Trade Commission so orders not to exceed 5 per cent. of the value of the use of the licensed subject matter as established by the Federal Trade Commisison.

A careful analysis of the legislation in this connection and of the rules for putting it into effect shows that an earnest effort is being made to ensure the welfare of the nation during a great emergency without infringing seriously the rights of enemy inventors.

We can confidently look forward to important industrial developments as a result of the recent legislation, developments which will do much to stimulate invention and further the expansion of our chemical manufacturers, freeing them from the former dependence upon Germany.

It is important to bear in mind that there is a notable differenec between the requirements for German and for American patents, especially in connection with chemical inventions. The main points are brought out in the following study of the subject made recently by the "Scientific American":

> Our Government has been very liberal to inventors. It has sought in every way to advance science and knowledge. The United States is one of the few coutries that is willing to give a patent to an inventor without requiring him to operate his invention within the country. Furthermore, we are very liberal in our manner of granting patents. are very liberal in our manner of granting patents. A patent is supposed to be granted to an inventor as a reward for advancing public information. An inventor is supposed to make a complete exposition of his invention so that the public may reap the benefits of it, and, as a reward for this disclosure, he is given a monopoly for a period of 17 years. However, there is a defect in our system which requires merely that the inventor disclose a workable process or machine and not necessarily a commercially practical one. German inventors have been quick patenting of chemical processes. They draw a distinction between "process" and "technique." As long as our statutes require merely that the process be disclosed the German inventor will make a disclosure of his chemical processes to an extent

just sufficient to come within our requirements, but will withhold, as trade secrets, many steps in the process which are essential to a commercial exploitation of the invention. Our statutes, furthermore, permit an inventor to patent separate steps in a process, and this the German inventor frequently does, thereby covering certain vital parts of his process which afford him absolute protection without disclosing the intermediate steps which are necessary to a full knowledge of the process of manufacture.

The German Government, on the other hand, insist upon a complete disclosure. The following abstract of the requirements in this respect, of the German law, furnished by Brandon Bros., shows how fully the applicant of a chemical patent in Germany must explain his process of manufacture:

"German applications for new processes of the manufacture of chemical preparations must be accompanied by a sample of these preparations, and also of the compounds used in the process, so far as such compounds may be new. These samples, which should weigh about 8 to 10 grams, should be put up in glass bottles of about 30 millimeters diameter and 80 millimeters entire height, closed with a glass stopper and having the seal of the applicant, and bearing an exact description of the contents.

"For coloring matter prepared from tar, a sample of dyeing on wool, silk, or cotton must be transmitted. These samples should be attached in a suitable way on a sheet of cardboard measuring 330 millimeters by 210 millimeters (13 by 8¼ inches). For each coloring matter, samples of dyeing in three different shades must be filed; for coloring matter permitting of quantitative analysis, one of those samples should be dyed with one per cent., and the other two samples might be weaker or stronger, according to the power of the dyeing matter. These samples must be accompanied by a description of the method of dyeing(distinctly give ing the degree of concentration of the dye liquor, the mordant, if any has been used, the temperature, etc., stating also whether the dye liquor has lost its color, or still contains more or less dye matter. Directions concerning the method of dyeing will not be published in the patent, except upon the special request of the applicant."

Thus while the German Government requires a complete disclosure of the "technique" of a process before granting a patent, it does not give out this disclosure to the general public. This increases the problem that faces us at the present time. The "Trading with the Enemy Act" enables our manufacturers to make use of German patents, and there are about 20,000 patents affected by the Act. But we find that many of these patents are not complete disclosures. Before our manufacturers can use them commercially much time and capital must be expended in experiment. This would deter our manufacturers from applying for licenses were they not assured that they would be permitted to continue to use the inventions after the war. The statute provides that unless the license is limited in term it shall last the life of the patent.

It will be evident thus, that this statute is not an act of confiscation except in so far as the enemy inventor will be obliged to permit the use of his patent even after the war, but will receive royalty for such use. We do not know what Germany is doing with American patents. Certainly Germany is not confronted with the same difficulties that we are. American patents in Germany have to do mainly with machinery and have no bearing on the health or safety of the nation. On the other hand, there are German patents in this country on salvarsan, veronal, novocaine, etc., which are important medicines. We must permit operation under these patents because they are necessary to the health of the people. If Germany should look upon the "Trading with the Enemy Act" as one of confiscation and attempt reprisal, we can do nothing until the end of the war when we shall demand adequate indemnities to settle for the losses of our own citizens.

Our Government is going to regulate the manufacture under the new Act, in the strictest possible way, requiring rigid inspection and submission of samples. It will, if necessary, even fix the prices, on articles necessary to the health of the military and naval forces as the successful prosecution of the war and require a reasonable price in all cases, because the purpose of this Act is not to enrich the manufacturer, but to benefit the public at large. In the matter of drugs, it is now proposed that the supervision and control of their manufacture be taken over by the United States Health Service so far as their inspection is required. No license will be permitted until the Board is assured that the manufacturer is capable of manufacturing the product in a satisfactory way, and at a price that will be fair to the public.

Swedish Dyestuff Industry.

Among the countries making a pronounced effort to attain material freedom from dependence upon the German dyestuff industry, Sweden is now to be enrolled. The consumption of synthetic colors is not very large, about 900 short tons annually. It is felt, however, that it is sufficient to warrant the establishment of a domestic industry, and a company has already been organized to finance the project.

Sweden lacks the raw material, as the country has no coking coal. It is, however, richer in chemicals than Switzerland which possesses a flourishing dyestuff industry despite her poverty in material.

The plans of the Swedish company embrace competition in foreign markets.

How the Government Views the Growth of American Chemical Industry.

Never before in our history have the various branches of the government devoted so much attention to the domestic chemical industry and to its wonderful possibilities. There is a general and generous recognition of the fact, that the present world conditions place it within our power to expand the industry at a rapid rate, to make it capable of meeting the great bulk of home demands and to win a place in foreign markets which can be maintained when European competition again comes into play.

The far-reaching fiscal legislation of September, 1916, in the interests of American coal-tar chemicals has paved the way for capital and enterprise to enter upo nthe manufacture of artificial dyestuffs, of synthetic medicinals and allied products, with a degree of confidence which assures final success. The fact that for the time being and for an indefinite period in the future, American consumers of colors are forced to rely upon the domestic output, affords the needed opportunity for establisting those confidential relations between manufacturer and purchaser which are all important for the future of the industry, and which, under normal conditions, could be attained slowly and at great cost, in the face of bitter foreign competition.

These facts and the intimate connection between the production of high explosives and the manufacture of coal-tar colors are now fully recognized by the authorities at Washington and there is a hearty readiness on their part to do all that is necessary to further the good work.

The Secretary of the Interior, in his annual report, devotes an unusual amount of space to our chemical industry, and from his summary of what has been accomplished the following may be quoted:

!ée(.c,v!!!! shrd lucmfwyp shrdl cm vbgkqjvbgk

"Before the war 90% of the artificial colors and dyes were imported, five or six concerns with 400 operatives producing 3,300 short tons per year. Now there are over 90 enterprises, each making special colors, and 100 concerns making crudes and intermediates.

"Sulphuric acid, the chemical barometer, has doubled in production. In 1916, 6,250,000 tons of 50 deg. Be. were produced. The estimate for 1917 is much greater, and the production for 1918 will again greatly increase.

"By-product cooking doubled its capacity in the last three years, yet in 1918 the United States will make half her coke in beehive ovens. Light oil, which contains the benzene and toluene needed for explosives, jumped from 7,500,000 gallons in 1914 to 60,000,000 gallons in 1917, and is again being largely increased. Ammonia production has increased 100% in three years and the visible supply is insufficient to meet the demand.

"Gasoline production has increased from 35,000,000 to 70,000,000 barrels per annum since 1914.

"Potash importation from Germany was stopped by the war, which has stimulated production in this country. The production from January to June, 1917, was 14,023 short tons of potash. This is a small production, but sodium salts have been substituted for almost all purposes except agriculture. Shortage of labor and coal is seriously interfering with the potash-brine evaporation in Nebraska, which was yielding about 90 tons per day.

"The production of explosives and consequent consumption of nitric acid has increased enormously. The nitric acid is still almost entirely made from Chili saltpetre, but synthetic nitrogen plants are under process of construction, and we have large quantities of coal-tar ammonia which can be used for munitions if necessary.

"Before the war 40,000 tons of barite were imported from Germany for the manufacture of lithopone. Now five companies are producing this article from deposits in Tennessee, Kentucky, Virginia and Missouri.

"American chemists have met the country's needs as ably and completely as did the chemists of Germany. We can go forward with every confidence that there will be no serious shortage of the many chemical products required for domestic consumption."

The new Tariff Commission devotes an even larger portion of its annual report to this subject. It fully recognizes the fact that the most important field for its activity will be in connection with adequate legislation to ensure the continuous expansion of our chemical industry and its future permanence. The industries, says the Commission, "will have to face new conditions on the conclusion of peace. In some branches there will be surplus capacity and a probability of sharp international competition." Surplus capacity will exist where acids and other substances have been produced in great quantities for munitions. Demand for these will be cut down. But there should be no reduction of the output of chemicals, drugs, dyes, etc., now made here in place of those imported before the war.

There is evidence in the annual reports that the importance of preserving and defending the new industries hereafter, when peace conditions are restored, is clearly seen at Washington. They should be fostered not only because they have made us independent of the old foreign sources of supply, but also for the reason that their growth has involved the saving of much valuable material which we formerly threw away, at the coke ovens, smelting mills, and elsewhere.

With this attitude at Washington, which reflects general political opinion, quite irrespective of faction or party, we may look forward with full confidence to the future. Should additional legislation be required to protect certain branches during the formative stage, it will encounter no serious opposition. The nation is determined to emancipate itself definitely and finally from dependence upon Germany for its chemicals as well as for many other articles. The possibility of attempts to throttle the young and growing industry by resorting to the methods of "unfair competition" on the part of foreign rivals, is now effectively precluded by adequate legislation. At the same time the extent to which capital has been invested in our chemical industry, especially in the manufacture of coal-tar products, assures consumers that there will be free play of competitive effort in meeting the needs of the domestic market.

Efficiency of American Color Chemists.

There has been an assumption by many that American chemists are not fitted temperamentally or by training to deal effectively with the problems connected with the symmetrical building up of our national dyestuff industry. This prejudice is fast disappearing in the face of accomplished facts, although, in fairness, we must recognize the valuable assistance rendered by chemists of Swiss, German and Alsatian origin.

The head of one of our largest color firms recently stated that he could detect no difference in professional ability between the young chemists employed in his laboratories of American birth or of foreign origin.

In a recent issue Cotton (of Atlanta, Ga.) outlines the reasons for the widespread opinion cited above. We quote:

"As to the misunderstanding regarding the American chemist and the former popular belief in his inferiority in the dyestuff line, this is easily understood. It should be noted that chemistry is divided into two distinct branches, organic and inorganic, and in Germany the principal and most important industry is the making of dyestuffs (which is organic chemistry). Most German students in chemistry after graduation seek positions in coal-tar plants, as there are no mines in Germany, and, therefore, less call for general chemists of the inorganic line. The universities naturally cater for the desires of the students and the wants of the country, and, therefore, the principal courses are organic chemistry, while the shorter courses are inorganic.

"In this country it is exactly the reverse. We had no dyestuff plants, but did have large industries of every other line, most of them requiring inorganic chemists. We called for technical men for our copper mines and refineries, iron works, and for heavy inorganic chemical plants. Therefore, the demand being for inorganic men, our universities and technical schools taught mostly inorganic chemistry, and our chemists averaged higher than the Germans in this branch of the science. Nevertheless, Americans who took up organic and dyestuff chemistry in former years had not the slightest trouble in mastering the science, and I recall that one of the chief chemists in the largest dyestuffs plant in Germany for a number of years was an American.

"Not only have we crossed the tape in the dyestuff line, but we have actually gone ahead in the working of vegetable oils (another branch of organic chemistry). Before the war all high-grade soluble oils for textile work were made from castor oil, mostly from Germany, and known as monopol oils (a German patent), or made in this country from imported castor oil. Today one Philadelphia concern is making a hydroxy oil which is made on an American process from American oils exclusively, and is superior to the heretofore imported product."

The Profits of European Dyestuff Companies.

It is a fact of some interest that the great German dyestuff companies, despite the cessation of most of their export trade, report a volume of business and a rate of profit quite equal to the figures of normal times, and in some cases even a marked advance is indicated. The same conditions exist in the rival industries of Switzerland, France and England.

In the case of the German works, it would appear that the actual production of colors is for the time being a purely secondary consideration. Their efforts have been concentrated, since 1915, chiefly on the manufacture of munitions and of hospital supplies, as well as of the many accessory chemicals needed for military purposes. During the close of 1914 and for part of 1915 there was a marked set-back in the activity of all the establishments. For the past two years, however, their productive capacity has been pushed to the utmost. This fact is quite evident from the annual reports issued during 1917, covering either 1916 or portions of 1916 and 1917. As a rule these reports do not reveal much of what is actually being done in the various plants, but confine themselves to financial results. Most of the companies make generous provision for sinking funds and operatives' welfare funds, and considerable amounts are placed in reserve for the uncertainties of the period immediately following upon the end of the war.

The largest German company, the "Badische

Anilin und Soda-Fabrik," reports profits of $6,300,000, as compared with $4,720,000 during the preceding year. The dividend rate was raised from 20% to 28%. The company placed $710,000 in its reserve fund and contributed $500,000 to the relief of crippled soldiers. An important acquisition during 1916 was the stock of the large lignite mine at Rattmansdorf with extensive plants for the manufacture of briquettes, paraffin and heavy oils. The company produces synthetic ammonia, by the Haber process, on a vast scale, and the nitric acid obtained from this by oxidation, according to Ostwald's method, is the chief factor in assuring the ability of Germany to meet the huge demands for powder and explosives required in her military operations.

The "Farbenfabriken vorm. Friedr. Bayer & Co.," of Leverkusen, reports profits of $5,100,000. A dividend of 28% was declared on the capital of $13,000,000. This is the same figure as in 1912 and 1913. In 1914 the rate was 19% and in 1915 20%. The company had added $1,300,000 to its reserves. It gives, also, $500,000 to the fund for crippled soldiers, and remembers generously the children of all its employes killed in the war.

The "Farbwerke vorm. Meister Lucius & Brüning," of Hächst, earned $5,760,000, as compared with $3,700,000, the year before. The dividend rate was raised from 20% to 25%. Synthetic medicinals constitute an important feature in this company's output.

The "Actien-Gesellschaft für Anilin-Fabrikation," of Berlin, reports profits of $1,740,000, as compared with $1,200,000 in 1915. Its dividend was also 25%.

"Kalle & Co., Aktiengesellschaft," of Biebrich, reports a gross revenue of $720,000 against $1,030,000 the year previous. Of this but $310,000 was devoted to dividends, the rate being 10% as in preceding years. The amount of $170,000, paid by this company in the form of taxes, throws an interesting sidelight on the burden of taxation in Germany at present.

The "Chemische Fabriken vorm. Weiler-Ter Meer," of Merdinger, earned $520,000, an advance upon the sum of $350,000 in 1915. The dividend rate was 12%.

The "Farbwerk Mühlheim, vorm. A. Leonhardt & Co.," of Mühlheim, reports a profit of but $43,000 and paid a dividend of 4%.

Two of the leading companies, "Leopold Cassella & Co.," of Frankfort, and the "Chemische Fabrik Griesheim-Elektion," also of Frankfort, have not published their annual reports. Both, especially the latter, have been, however, very active.

A few of the other prominent German chemical companies might be mentioned in this connection, in order to present a more complete picture of conditions in the Empire.

The "Deutsche Gold und Silberscheide-Anstalt," of Frankfort, reports a gross revenue of $2,700,000 ($2,400,000 in 1915). Its dividend rate was 27% and $1,200,000 was placed in the reserve fund.

The "Vereinigte Chemische Fabriken," of Mannheim, paid a dividend of 27½% on its capital of $1,200,000.

The "Chemische Fabrik Schering," of Berlin, largely devoted to medicinal and photographic products, paid a dividend of 16% (12% in 1915). It carries a reserve of $1,200,000, over three times the amount of its profits for the year—$380,000.

The "Chemische Fabrik von Heyden," of Dresden, earned $930,000, over double the profits of 1915, and paid a dividend of 25% on its capital of $1,470,000. This company has erected, near Görlitz, large works for making nitric acid from atmospheric nitrogen.

The "Saccharinwerke Fahlberg, List & Co.," earned $280,000, as compared with $180,000 in 1915. The dividend rate increased from 10% to 12%.

Establishments devoted exclusively to the manufacture of explosives have naturally earned large amounts. The leading representative in this class, the "Verenigten Köln-Rottweiler Puloverfabriken," had a net revenue of $3,500,000, about the same as in 1915. The dividend that year was 35%. This was decreased to 20%, while $1,200,000 was added to the reserve fund and $1,700,000 was carried to the next year's account.

This summary statement gives ample evidence that the chemical industry of Germany, while earning exceptionally high profits, is displaying a careful, conservative caution in accumulating heavy reserves. The question naturally arises as to the extent to which these reserves have been invested in Government bonds, and the prospective value of such investments when the war ceases.

General confidence in Germany in the future of the dyestuff industry is, however, manifested by the continued high quotations of the stock of the leading companies. The "Badische" and "Bayer" are quoted at 630; "Hoechst" at 540; "Actiongesellachaft," Berlin, at 525; "Griesheim-Elektron" at 470, and "Weiler-Ter Meer" at 280.

It is quite pertinent in connection with the above survey to briefly note the status of the dyestuff industry in the other European countries.

The leading Swiss company, "La Société pour l' Industrie Chimique" of Basel reports for 1916-17 a net revenue of $1,620,000 on a capital of about $2,000,000, after generous provision for sinking funds, funds for pensions, etc. The dividend of 25% was supplemented by a bonus of 250 francs per share (presumably of 1,000 francs). The income in 1915-16 was less than two-thirds of the above amount, and the dividend rate was 24%.

The "Chemische Fabrik vorm. Sandoz & Co.," of Basel, reports an even more prosperous year. Its net income was $1,850,000. Its dividend of 25% was supplemented by a bonus of 1,000 francs per share (presumably on shares of 1,000 francs) as was also the case the year before.

The other two companies in Basel, "Farbwerke vorm. L. Durand Huguenin & Co.," and "Anilinfarben und Extract-Fabriken vorm. J. R. Geigy," report likewise a prosperous year, although details are not furnished.

The results obtained in Switzerland are all the more creditable, and even astonishing when it is borne in mind that the little republic is totally dependent upon outside sources for its fuel and for the raw material required in the coal tar chemical industry.

In France the leading company engaged in the production of colors is "La Société des Matières Colorantes et Produits Chimiques de St. Denis." Its profits in 1916 were $730,000, as compared with $522,000 the year previous. The capital of $875,000 has been increased to $1,400,000.

"La Société Chimique des Usines du Rhône" has become a powerful factor, producing colors and a variety of chemicals. Its sales in 1916 exceeded $24,000,000. The profits were over $2,100,000. Of this sum $1,000,000 was placed in the reserve fund. In 1915 the amount reserved was $600,000. The sum available for dividends was $1,200,000 as compared with $80,000 in 1915.

"La Campagnie des produits Chimiques d'Alais et de la Camarque" is devoted to inorganic chemicals and explosives, and has a capital of nearly $8,000,000. Its profits available for dividends have increased in a rapid ratio. They were as follows: 1914, $477,000; 1915, $1,490,000; 1916, $3,700,000.

The smaller chemical companies in France which have rapidly established plants for the production of coal tar and other organic compounds, all report most satisfactory financial results.

In England the report of "British Dyes, Limited," is a fair barometer for the results currently obtained by the group of firms engaged in the manufacture of artificial colors. The capital is nominally about $10,000,000, although not yet all paid up. A large part is furnished by the British Government. After paying the interest on such advances, and making generous provision for sinking fund and new plant, a sum of $75,000 remained, which sufficed to pay a dividend of 6% on paid-up stock and to carry $20,000 to the current year's account.

While the figures for "British dyes" are exceedingly modest as compared with profits on the continent, there is every reason to believe that the color industry in England is thriving and is occupied rather with laying the foundations for the future than in seeking large, immediate gains.

And the steady, businesslike pursuit of this policy will surely furnish its own rewards later on.

Artificial Dyestuffs in Italy

Like other countries, Italy is studying the problem of creating a national coal tar color industry. The obstacles to be overcome are much more serious than in any other large European country, on account of the absence of coal in the Kingdom and the lack of development in the chemical industry as a whole. There is, on the contrary, a rather large demand normally for dyestuffs and a growing desire to be independent of German sources in the future.

Dr. A. Bolis, in a recent number of "L'Industria Tessile e Tintoria," analyzes the situation quite fully. He emphasizes the necessity of adequate tariff protection, showing numerous anomalies in the present schedule of duties. Thus the duties, per 100 kilos, on benzine and toluene are $4.75; on most intermediates, $2.00; on benzaldehyde, $60.00. Aniline, toludines and finished colors are free of duty.

His conclusions are as follows:

1. Raw material must be exempted from an entrance tariff, while the intermediate and finished products should be charged entrance tariffs, higher in the latter case than the former.

2. The entrance tariff should be regulated in accordance with the fineness or quality of the products and with the number of the manipulations necessary for their manufacture.

3. The customs tariff should be more rationally arranged and be more detailed. No customs entrance tariff will be an assistance to the industry unless the fiscal arrangements are modernized with a view to the present necessities of the countury.

The necessity for this scientific and well-balanced protection he advocates in another paragraph:

"To be able to exist and prosper, the industry of synthetic coloring matters must have more than a hand-to-mouth existence; it must find itself in conditions of real prosperity. An essential factor is its continual development; it should be progressive and inevitable, founded on a rigorously scientific basis and requiring an incessant study of every element of progress and of every possible improvement. The industry to have a chance of life must show good balance-sheets; if the large German works had not made large profits, they could never have developed their admirable technical and scientific organization, and without this it would have been impossible for them to survive and prosper continuously."

Dr. Bolis looks forward to an intense competitive struggle, at the close of the war, in the effort to control the trade in synthetic dyes. His remarks in this connection, coming from one quite closely in touch with existing conditions, are worthy of careful reading, especially as they bear upon the

THE COST OF CREATING A MERCHANT MARINE

By JOHN PRICE JONES

Two billion dollars for a new merchant marine is the grimly determined reply of the United States to the U-boat ravages of the German war autocracy. Although the Hun has torpedoed to ocean bottom nearly 8,000,000 gross tons of shipping flying the various flags of the Allies, America, unafraid and defiant, has consecrated this mighty sum to the resurrection and rehabilitation of the power represented by these sea-buried messengers of commerce. Systematized Liberty Loan campaigns are the great forces that insure the aggressive rebuilding that is now a critical necessity.

There was time when $2,000,000,000 would have seemed a sum too staggering for even intense patriotism to appropriate. Nothing is too costly that is dedicated to the preservation of freedom, but sentiment alone cannot carry on wars. To replace a vanished 8,000,000 tonnage requires immediately vast sums and vaster sums in addition to expand the shipping of the United States to meet the demands of trade after this great conflict has ceased. The coming third issue of Liberty Loan bonds points the way that this patriotic desideratum, thus far so nobly advanced, shall be carried on to glorious fruition.

It was in the Urgent Deficiencies Appropriation Act of June 15, 1917, that the determined purpose of the Government to replace its vanished shipping and prepare for a top-notch place in the struggle for commercial supremacy after the war, was made manifest. An item was included—it seems droll to call it such but so it has been legislatively designated—an item authorizing the purchase, requisitioning and acquisition of ships, materials, plants and charters on ships. This item was for the sum of $250,000,000—a fairly good intimation to the torpedo sea-assassins of Germany that Uncle Sam intends doing things.

And along a little further in the act came another item of $500,000,000 for the construction of ships, making the total appropriation for the new merchant marine at this one time three-quarters of a billion of dollars. It was a momentous day in American appropriative history. It marked a new Declaration of Marine Independence for the United States of America. The editors of Hun propaganda across the water took immediate notice. Their attempts to belittle the importance of the event only revealed the more their secret apprehensions.

Again, on August 3, 1917, the United States Emergency Fleet Corporation gathered to its control every vessel then building in the shipyards of the entire country, of 2,500 or more tons deadweight carrying capacity. Automatically above 400 vessels in various stages of construction were taken over. They aggregated more than 2,800,000 deadweight total tonnage. It was another forceful defi to Kaiserdom and Junkerism. Immediately construction went ahead at full speed with every hour of overtime in the work that could be crowded into the twenty-four of the work day. The echoes of the rivet hammers were heard in pounding rivalry to the malevolent work of the U-boat makers at the German sea-murder base.

To reimburse the owners of these vessels so taken, the sum of $265,000,000 was needed additional to the amounts already appropriated. This was authorized by subsequent legislation. It was forthcoming through the patriotic outpouring of Liberty Loan money by the free men and women of America.

To this magnificent initiative in the genesis of the United States merchant marine in this world war epoch, the Shipping Board made available a total of $550,000,000. This, too, Liberty Loan money put to its most effective use in an urgent hour. Up to September 22, 1917, by this authorization, contracts had been let for the construction of 636 ships with a total tonnage of 3,124,700. There will be 353 wooden ships, 225 of steel and 58 composite. The ratio of the Kaiser's recent U-boating to this mighty new commercial fleet is small almost to the point of negligibility.

Lastly in the way of cost of America's new merchant marine, legislation was introduced authorizing an additional $734,000,000 for new ship construction. There can be small doubt that the establishment of new tonnage in accordance with this mighty sum's possibilities, sounds the death knell of Germany's dreams of ocean trade supremacy. This sum will pay for the building of more than 8,000,000 tons deadweight in ships utilizable for trans-sea service. This means 5,000,000 tons in addition to the 3,000,000 now under construction and for which contracts have been let. Summarized as to effectiveness aside from cost, this is Uncle Sam's merchant marine challenge:

Ships under construction, requisitioned August 3, 1917—an aggregate of 400 of 2,800,000 deadweight tonnage.

Ships contracted for under the program for new

INDUSTRY IN WAR TIMES

An Unofficial Statement Regarding "Essentials" and "Non-Essentials"

By

GEORGE N. PEEK

Realizing the confusion which existed in the minds of countless manufacturers throughout the country as to the exact interpretation of the terms "essential" and "non-essential" as applied to the various industries, and being further aware of the unsettled and therefore harmful conditions which must necessarily obtain until some of the doubts regarding the probable future attitude of the Government toward certain industries could be set at rest, Mr. Waddill Catchings, chairman of the War Committee of the U. S. Chamber of Commerce, recently wrote to Industrial Representative George N. Peek, of the War Industries Board, Council of National Defense, asking him for an unofficial view of the matter in the absence of a definitely formulated policy.

Mr. Peek's reply, in part, follows:

"The enclosed statement 'Industry in War Times, or Essentials and Non-Essentials' reflects my views on this subject and the view of a number of my associates with whom I have discussed the matter at frequent intervals during the past two months.

"You understand that this is entirely unofficial and must be so regarded, but it occurs to me that it may be of some help to you in answering inquiries as to the attitude of some of the men in Washington upon this most important subject.

"My observation leads me to conclude that the various Governmental departments are giving the subject careful consideration in the hope that by carefully and considerately treating the whole subject confusion may be avoided."

Although not directly relating to the chemical industries of the country, the statement appended to Mr. Peek's letter has been deemed of sufficient interest to a large proportion of the readers of the Chemical Engineer to warrant its reproduction in this journal, and it is accordingly here given in full:

Mr. Peek's Statement.

Industrially, the first problem of the Government is to secure the necessary supplies for the conduct of the war without too seriously interfering with the production of necessities for the public welfare. The second problem is to insure continuance of our industrial strength after the war.

Shortages of many classes of raw materials and of labor in different lines are evident. Transportation, both water and rail, is obviously short, and the need of industrial readjustment is apparent to make room for the war requirements of our Government and our Allies.

These problems may be solved by making provision for the entire requirements of the Government in such a manner as to utilize to the fullest extent present productive capacity. In many cases the facilities of less essential industries should be converted to essential production.

Limitation of Non-War Industries.

The discussion of the "limitation of 'non-essential' industries" started with a very unfortunate misuse of words. The idea, as exploited in the newspapers, that the Government intended to cut off "non-essential" industries, had in it possibilities for disaster.

All industries are closely inter-related. For instance, certain so-called "non-essentials" may be sent to South America to pay for commodities absolutely needed for essential products and no large class can be arbitrarily cut off without seriously affecting general business conditions in the country. Certainly no industry is "non-essential" to the workmen and capital employed therein, and when one considers that over ten million people and thirty billion dollars of capital are employed by "non-war" industries the need of caution in dealing with this problem is manifest.

On the other hand, our industrial equipment is limited. We do not have materials, machinery, transportation, labor or capital sufficient for fighting the great war and for normal business at the same time. The war must be prosecuted to the utmost and business must shrink to provide the necessary equipment with the least possible injury to the business of the country.

The first consideration of the Nation and all of its industries must be to contribute the utmost toward winning the war, and to that end business must, where necessary, be diverted from its established channels into new channels; or if absolutely necessary, the flow must, during the war, be entirely stopped in order to provide adequate labor and material for war needs. It does not, however, follow that there will be less business than usual, but rather more unusual business.

If the so-called "non-essential" industries are "cut off" many of them would be ruined and others permanently crippled.

The Fuel Administration has worked out a plan which provides, in part at least, for necessary restrictions with the least possible injury to industries. This plan provides for fuel curtailment by the following steps:

1. **Voluntary agreement** by each non-war industry to limit the least essential parts of its product—each industry making the reduction where it will do the least harm.
2. **Formal order** from Fuel Administrator making legal and binding on the entire industry the various restrictions voluntarily agreed upon.

This plan applies directly to actual fuel consumption only. The actual effect is to limit production. Consequently, limitation in the use of fuel will make a corresponding saving in transportation and in the materials needed for the war. The fuel saved will vary according to the character of each industry.

The above plan has already been tried out enough to prove its practicability. In each case the industry has given its heartiest support and shown its desire to co-operate with the Government in every possible manner. The voluntary saving shown by the industries already called into conference promises to be 15 million tons of coal. The brewers have voluntarily agreed to save 700,000 tons of coal; the box board manufacturers will cut their running time to five days a week. This will save one million tons of coal and take 30,000 cars of merchandise off the railroads.

The Commercial Economy Board of the Council of National Defense has undertaken to co-operate with business men in eliminating, as the Government's requirements demand, needless uses of men, materials, equipment, and capital in all lines of commercial business; in other words, to conserve commercial resources as necessary to meet the Government's need.

The Board's policy is to work forehandedly. It investigates forthcoming supplies and demands, to see where shortage is threatened; then introduces such economies as will prevent the shortage, or keep it from becoming needlessly acute.

Co-operation of business men with the Board is voluntary. The Board can not compel adherence to its recommendations by legal process. In fact, its purpose is to make such compulsion unnecessary. It works on the theory that there are considerable needless uses of labor, materials, equipment, and capital in all businesses, and that by forehand action and with voluntary co-operation from business men enough of these uses can in most cases be eliminated to meet Government requirements without resorting to more drastic methods.

Of course, there are certain commercial and industrial resources which can not be handled adequately for the Government's purpose in this way. In urgent cases these resources must be diverted quickly from the less essential to the more essential uses, in whatever manner seems most effective. But in most instances, at least for the present, the voluntary methods described would seem to be sufficient.

The Board is now carrying on campaigns for conservation in several industries, including the manufacture and distribution of wool and woolen clothing, leather and shoes, and paint and varnish, and in the service of wholesale and retail stores. The Board is also making preliminary studies of other commodities in which, because of shipping or other conditions, there is a possibility of shortage.

Coal Production.

On acount of transportation conditions, the United States, according to the Fuel Administration, will probably mine little if any more coal in 1918 than in 1917.

1916 coal production approximately 575,000,000 tons.
1917 coal production approximately 630,000,000 tons.
1918 coal production estimated not to exceed 630,000,000 tons.

War industries and railroads must have at least 100,000 tons per day more than they had in 1917, or the flow of war necessities will be dangerously interrupted. This increase must be met by curtailment of the so-called "non-essential" production and by economy at every furnace door, both household and industrial.

The demands for 1918 to carry out the program for the production of necessities for the war, in addition to the normal business, would greatly exceed any possible production and distribution of fuel, so there is but one remedy, i. e., to limit the production of non-war industries sufficiently to provide for:

(a) War needs—direct and indirect.
(b) Necessities for the public welfare and domestic consumption.

In accomplishing the desired end, it should be our effort to divert the energies of non-war industries as far as possible to the production of the essentials for war, that each industrial center may use existing facilities, with its labor living at home, happy and contended.

In the readjustment process it is inevitable that the normal business of some industries must be interfered with in order that the production of war and public necessities be kept at the maximum. It may be that some plants, because of lack of power, shortage of labor, raw materials, or transportation, may have to suspend entirely. These sacrifices must be endured in the interest of our first object, which is to win the war. If we secure complete co-operation between Government and business, it is hoped that our industries may emerge from the disturbed condition caused by the war, intact and strong for the economic problems which must face us.

Duty of War Industries Board.

It would seem to be the immediate duty of the War Industries Board—

1st: To list, by classes or otherwise, and to define those industries whose operation as a war measure are of **exceptional importance,** classifying them as far as practicable in the order of their relative urgency, measured by the extent of their contribution, directly or indirectly, toward winning the war.
2nd: To consider carefully and, after due notice

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS.*

PART XII

Keyes' Apparatus.

An apparatus for treating oils, milk or other substances which are not transparent to them, with ultra violet rays, is disclosed by *Keyes* (U. S. Pat. 1,235,698, Aug. 7, 1917). The liquid to be treated is fed from the top of the apparatus (See *Figure* 1) and allowed to flow down over the screen in thin layers, where it is exposed to the light and is collected in a trough in the bottom. The screen may be made of metal or of fibrous material, depending on the character of the liquid being treated.

Heyl (Chem. Abs., 1918, 103; Dan. Patent, 22,258 and 22,269, July 16, 1917) proposes to dry waxed leather by exposing it to the action of ultra violet rays in the presence of ammonia derivatives, hydrazine or nitrogen.

Celluloid Substitutes.

Details of the production of useful products by the polymerization of vinyl esters when employing the mercury vapor lamp or other source of light are given by *Klatte* and *Rollett* (U. S. Patent 1,241,738, Oct. 2, 1917. Chemische Fabrik Greisheim-Elektron). The polymerization can be accelerated by catalyzers, benzoyl peroxide, oxonides, and anhydrides of organic acids in conjunction with an agent giving off oxygen (perborates, percarbonates, silver oxide, etc.) being mentioned for the purpose. The polymerization products, which form more or less rapidly in accordance with the intensity of illumination and the temperature, are solid, colorless and transparent celluloid-like masses which are odorless and can be turned, cut, planed, and otherwise manipulated to form various articles. The solid masses obtained can be rendered plastic in hot water and then be molded and, after cooling, the mass becomes again hard. In order to obtain special effects the initial materials may be mixed, prior to exposure to light, with other bodies or conditioning agents, such, for instance, as camphor or coloring matters.

Chlorinated esters may be polymerized by heat and light as a two-stage operation in the following manner: 1 kilogram of vinyl chlor-acetate is mixed with from 0.5 to 1 gram peroxide of benzoyl and carefully heated in a large vessel provided with a reflux condenser. At from 80° to 100° polymerization takes place, while the temperature rises rapidly. At this time care should be taken to cool the reaction vessel. The violence of the reaction may be modified by diluting the reaction liquid with an indifferent solvent; for instance, in the present example, about 300 grams of chloro-benzine can be used. The reaction product is a viscous syrupy mass, which can be further treated by exposing to light without a diluent, solid masses being obtained as the remaining unaltered vinyl ester polymerizes. The syrupy solution or a solution made from the completely polymerized ester may be used as a lacquer or other coating compound. When allowed to dry in thin layers, colorless films of a celluloid-like nature are obtained. Vinyl chloride may be polymerized by ultra violet rays, but the product derived is not as satisfactory as that obtained from the esters mentioned.

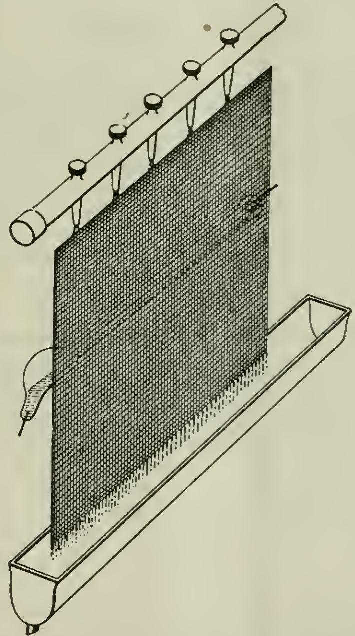

Fig. 1—Keyes' apparatus for the exposure of opaque liquids to ultra violet rays.

Preparation of Catalyzers.

A process for activating catalysts for use in hydrogenating unsaturated fatty acids and their glycerides is described by *Utescher* (U. S. Pat. 1,124,560, Jan. 12, 1915). The metal to be used as a catalyzer is treated with hydrogen and at the same time exposed to the action of the rays from a mercury vapor lamp or to a silent electric discharge. It is claimed that by this treatment the metal is atomized and made very active.

---

Spent catalyzer is claimed to be revivified by being treated in this manner after the fat has been burned out.

Chlorination of Natural Gas.

The chlorination of natural petroleum gas under the influence of the rays of a mercury lamp has been investigated by *Tolloczko* (Chem. Abs. 1914, 1282; Abhandl. Krakauer Akad. Wissensch., 52, 307-16; Chem. Zentr., 1913, II, 99-100). The chlorination was carried out in the outer coat of an ultra violet lamp set up in the form of a Liebig condenser. No explosions resulted, even when the proportions of chlorine and natural gas were the same. The temperature varied between 80° and 100°. In the chlorination with an excess of the natural gas (natural gas: chlorine=1 : 2) the velocity of the gas stream was 4 liters per hour. A yield of 1.18 grams oily and 0.24 grams gaseous products was obtained per liter of gas. With a double passage of the gas through the walls of the ultra violet lamp these yields increased to 1.53 grams oily and 0.38 grams gaseous products per liter. The volatile portion consisted chiefly of methyl chloride and dichlor methane. By fractional distillation the oily products were separated chiefly into dichlor methane, carbon tetrachloride, dichlorethane and tetrachlorethane. In chlorination with an excess of chlorine an oily product and solid hexachlorethane were obtained.

Chlorination of Hexane and Heptane.

Graul and *Hanschke* (U. S. Patent 1,032,822, July 16, 1912) produce halogenated paraffin hydrocarbons by mixing the hydracarbon with chlorine in the dark and then exposing the mixture to ultra violet light. Directions are given for making chlorhexane and heptane as follows: Normal hexane is boiled in an enameled vessel, on the water-bath, and the vapors pass through a vertical fractionating column into a second vessel into which chlorine is led at the same time and in which the mixture of the components takes place. The mixture containing an excess of hexane vapor passes into a third vessel in the middle of which a mercury lamp is burning. The vapors leaving this reaction vessel are passed through a condenser in which the chlorhexane and the excess of hexane condense and pass through a siphon into the distillation vessel, while the hydrochloric acid formed during the process is allowed to escape from the circuit. The fractionating column attached to the first vessel is maintained at such a temperature that only hexane is allowed to pass, while chlorhexene remains in the distill-vessel and increases in quantity. To prepare monochloriso heptane, Galician petroleum of B. P. 88-92°C. is purified as far as possible by repeated distillation and extraction with sulfuric acid, affording a fraction which consists chiefly of isoheptane. This is placed in a lead lined vessel provided with fractionating column and raised to the boiling point, at a pressure of 50 mm. of mercury. The vapors are mixed with chlorine and passed through a vessel containing a mercury lamp, whereupon chlorination takes place. In order to chlorinate 10 parts of hydro-carbon, about 7 parts of chlorine are necessary. The chlorination product consists chiefly of a monochlorisoheptane which boils at about 140° C. and contains, according to analysis, 26.5% of chlorine. By treating, in a similar manner, the repeatedly purified fraction of Galician petroleum which boils at from 75° to 81° C., a product is obtained boiling between 135° and 145° C., and containing 29.1% of chlorine, while pure monochlorhexamethylene contains theoretically 29.8% of chlorine.

In the writers' laboratory, a number of experiments have been made to compare the production of benzyl chloride, benzal chloride and benzo trichloride by the chlorination of toluol under various conditions. The best results were obtained by passing an excess of toluol vapors mixed with chlorine through a transparent quartz tube while exposing to the action of the ultra violet light. The product was withdrawn from the reaction tube and the contents were collected and fractionated, the unused toluol being returned through the reaction tube. In order to determine the effect of the ultra violet rays on this reaction the source of light was removed and the experiment carried out in the same manner as described above. The results of one test are given in the accompanying table.

Fraction	Quartz Tube without U. V. Light	Quartz Tube With U. V. Light
A. Up to 150°C.	72%	42
B. 150- 170°C.	4.2%	2
C. 170- 185°C.	18.5%	47.5
D. 185- 215°C.	3.8%	6.5

Sterilization of Water.

A description of the plant and operation of a large pressure type ultra violet water sterilizer at Henderson, Kentucky is furnished by *Smith* (Engineering News Record 1917, 1021). The water delivered to the sterilizer is first passed through settling and coagulating tanks then through mechanical filters before reaching the sterilizer. The source of water supply is the Ohio river; the raw water is pumped into two coagulating basins 95 ft. long, 30 ft. wide and 16 ft. deep, where it is stored for 4 hours, then into two baffled mixing chambers 25 ft. long, 7½ ft. wide and 17½ ft. deep, and from there into six reinforced concrete filter units 17 ft. long and 13 ft. 4 in. wide with a normal capacity of 625,000 gallons each per day. The ultra violet sterilizers consist of three legs each, (Fig. 2,) comprising five units. The legs are connected in parallel and the entire equipment is connected in series with the pipe line leading from the filtered water basin to the storage for the city supply. Each unit has a lamp box inserted in the side equipped with a clear quartz closed end tube which projects into the body of the unit and around which the water is forced in a thin film by means of a baffle placed at 90° to the long axis of the sterilizer. The quartz tube is contained in a slotted opening in the baffle. The lamp proper is a 220 volt direct current mercury vapor arc lamp and is designed to be automatically tilted by a special support located in the lamp box. The individual lamps are so connected that they may be adjusted individually and are also connected to the main switch board, each lamp having a "tell tale" incandescent lamp and a warning bell to notify the operator in case any of the lamps are not functioning properly. The following table shows the efficiency of the installation on which daily tests were made for over two months:

TYPICAL RESULTS, BACTERIAL TESTS AT HENDERSON WATER-PURIFICATION PLANT.

Sample	Total No. of Samples	Bacteria per c.c., 24-hr. Incubation — Total Bacteriar — Maximum	Average	B. Coli — Maximum	Average

Rate of pumping 2,200,000 gal. per day to 3,200,000 gal. per day, with little or no variation in results.

Turbidity of raw water varied from 130 to 880 r.p.m.

Filtered water usually clear with maximum turbidity of 5 r.p.m.

The rate of pumping was 2,200,000 to 3,200,000 gallons per day with little or no variation in results. The turbidity of the raw water varied from 130 to 880 p.p.m. The filtered water was usually clear with a maximum turbidity of 5 p.p.m. The plant has been operating for some months under a varying capacity of from 2,200,000 to 3,500,000 gallons per day at an expenditure of 92.5 kilowat hours per million gallons.

Mason (Water Supply, page 202, published by John Wiley & Sons, 1916) shows a type of ultra violet installation for sterilizing water on a large scale. The efficiency of this type of apparatus as compared with other methods of sterilization is given. It is concluded that in case the water is clear (not turbid) it may be efficiently sterilized by this method and that the color of the water is not a serious hindrance to proper sterilization, but that turbidity, whether caused by organic or inorganic material, diminishes the sterilization. It is also stated that a rather high velocity of the water passing through the sterilizer is preferable as agitation is beneficial for securing high sterilizing efficiency.

Newcomer (J. Exp. Med., 1917, 841-8) in discussing the abiotic action of ultra violet light states that typhoid bacilli are about 1/200 as sensitive to ultra violet light of wave lengths 2100-2800 Angstrom units as is the photographic plate. Their sensitivity to longer waves decreases rapidly to almost zero at about 2970.

Transparency of Media.

The absorption of ultra violet light has been discussed by *Luckiesh* (Met. & Chem. Eng., 1918, 232). The spectrum is divided somewhat arbitrarily into four regions as follows: Visible spectrum extends to wave lengths slightly shorter than 400 $\mu\mu$; near ultra violet. 400 to 300 $\mu\mu$; middle ultra violet, 300 to 200 $\mu\mu$ and the Schumann region, 200 to beyond 100 $\mu\mu$. The transparency of various substances to light waves of short length may be summed up as follows:

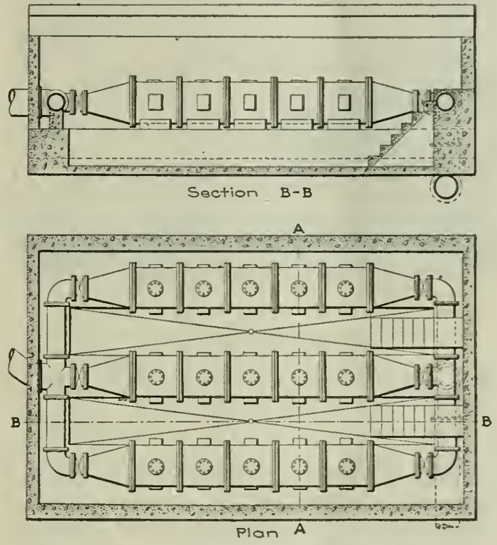

Fig. 2—How the municipal water-sterilization plant at Henderson, Ky., was laid out, showing the three parallel five-unit legs. (Courtesy R. U. V. Co., Inc., N. Y.)

Ordinarily clear glass is quite transparent down to 350 $\mu\mu$, but is practically opaque at about 300 $\mu\mu$. Special glasses have been made, however, which are transparent as low as 185 $\mu\mu$. For example, glass composed of 6 parts calcium fluoride melted with 14 parts of boric anhydride is recommended. Fused quartz is transparent as low as 180 $\mu\mu$. Fluorspar is transparent to 120 $\mu\mu$, but as the atmosphere absorbs these short rays very readily it is necessary when using such rays to take special precaution against absorption. Gypsum, celestite, borite, sugar crystals, calcite, and alum are transparent to about 170 $\mu\mu$. Rock salt is transparent to 185 $\mu\mu$. Mica and gelatine absorb the very short waves and therefore cannot be used when working below about 200 $\mu\mu$.

As it is sometimes desired to work with waves of restricted length, various substances may be used either singly or in combination, so that all but the desired waves may be absorbed. For example, copper sulphate, methy violet, chlorine, bromine, alkali metals dissolved in ammonia and various other substances may be used in solution in cells or mixed with gelatine and coated on plates. According to Luckiesh, Absalom (Phil. Mag. 1917, *33*, 452) gives the following table showing the wave lengths which are completely absorbed by certain substances.

Natural blue rock salt	Beyond 225 μμ
Natural rock salt colored by cathode rays	Beyond 225 μμ
Natural rock salt colored blue by cathode rays	Beyond 225 μμ
Sylvite, white	Beyond 225 μμ
Chili saltpetre, ordinary white variety	351.2 μμ
Chili saltpetre, violet	324.8 μμ
Fluorspar, colored deep violet by cathode rays	Beyond 225 μμ
Diamond yellow	320 μμ
Diamond blue	315 μμ
Kunzite	305 μμ
Garnet	402.3 μμ
Zircon (hyacinth) red-brown	261.8 μμ
Zircon, decolorized by heat	244.2 μμ
Zircon, green	402.3 μμ
Zircon, yellow	402.3 μμ
Topaz, pale yellow	261.8 μμ
Topaz, dark yellow	229.4 μμ
Topaz, pale pink-brown	261.8 μμ
Topaz, blue	296.1 μμ
Emerald	320 μμ
Ruby	300 μμ
Tourmaline, green	351.2 μμ
Tourmaline, green-yellow	300 μμ
Tourmaline, pink	306.4 μμ
Spinel, blue	402.3 μμ
Spinel, purple	324.8 μμ
Spinel, pink	300 μμ
Kyanite, blue	320 μμ
Beryle, blue	327.4 μμ
Cordierite, blue-purple	324.8 μμ
Cairngorm	324.8 μμ

Liveing and *Dewar* (Proc. Royal Society, London 1883, 71) have made measurements of the wave lengths absorbed by various substances. The source of light was an iron arc in most cases, although other electrodes were used. A spectroscope having quartz lenses was used for making the operations. Gases were enclosed in tubes which had either quartz or rock salt plates at the ends and liquids were placed in cells having quartz sides. Chlorine, bromine, iodine, hydrogen sulphide, carbon trisulphide, carbon tetrachloride, chlorine peroxide, chrome alum, mica, silver, gold and iceland spar were examined and the wave lengths absorbed given. The lines of absorption vary with the density of the solution, varying from 2500 to 4000 Angstrom units with the greatest proportion lying between 3000 and 3500.

Kron (Ann. Physik. *45*, 377-98, 1915) discusses numerous measurements of the limits of ultra violet solar radiation recorded at various distances to determine the degree of extinction of such radiation by the atmosphere. The limit of effective rays is near 3250.

If photographic methods which exclude visible light rays were applied to various physical phenomena, *Wood* (Smithsonian Institute 1911, 155) states that new facts would probably be discovered. In order to accomplish this exclusion, suitable screens must be employed. Glass lenses cut off invisible rays, while quartz lenses coated with metallic silver cut off visible rays, but allow the invisible rays to pass. Dense cobalt blue cells filled with a solution of potassium bichromate make possible photographs in infra red rays. Infra red rays are not scattered by the atmosphere, while ultra violet rays are so scattered that it is unlikely that any of them reach us from the sun, but that such rays as do reach the earth come from the sky; uranium nitrate shines when exposed to ultra violet rays, while vapors of mercury may be seen rising from a body of mercury even at room temperature when photographed in ultra violet light.

Sterilization and Absorption.

In the experiments of *Browning* and *Russ* (J. S. C. I.; 1917, 1146; Proc. Roy. Soc., 1917, 33-38; Chem. Abs. 1918, 187.) a tungsten lamp and a quartz spectometer, giving wave lengths of 7000-2100 Angstrum units, were used. A glass plate coated with nutrient agar was painted with an emulsion of Staphylococcus pyrogenes aureus, and a narrow strip of the plate was exposed to the rays from the lamp for 6, 12, or 24 minutes. The plate was then incubated It was found that there was a germicidal action on that part of the strip exposed to rays of wave lengths 2940-238C units. The longer exposure only very slightly increased the range of germicidal action. Exposures of 3½ hours gave a sharp line of demarcation at 2960 units, the other limit being 2150 units. Plates of Bacillus coli communis, B. typhosus, acid fast bacillus (timothy grass B) and meningococcus were also exposed to the rays, and the range of action was found to be nearly the same, although there were small and definite differences in each case. Emulsions of the organisms were also exposed to the rays and photographs of the radiations transmitted were taken. It was found that absorption of the rays took place over the same range that gave the germicidal action. Rays with wave lengths between 3800 and 2960 A. had no marked germicidal action, but were able to penetrate a considerable thickness of human skin. Rays with wave lengths from 2960 to almost 2100 A. had a very marked germicidal action, the maximum effect being obtained between 2800 and 2540 A. These rays however, possess but little penetrating power, being completely absorbed by as little as 0.1 mm of human skin.

Visible light rays are not as a rule absorbed by protoplasm is the conclusion of *Harris* and *Hoyt* (Univ. Cal. Science, 1917, 818-20); hence their action is usually confined to specialized pigment areas which constitute the receptive elements of optical sense organs. Ultra violet light is generally highly toxic even for colorless organism, and since this toxicity probably depends upon photochemical reactions the question raised is, to which constituent of the protoplasm is to be attributed the selective absorption of these rays and which is the necessary precedent to their photochemical activity? Experiments were made to determine the time in seconds of exposure to the direct rays of a Cooper-Hewitt ultra violet light, type Z, at a distance of 12 centimeters from the quartz tube. It was proved that the normal extermination period for washed paramecia suspended in water was about 100 seconds and that the organisms were not affected by the gases, ozone and nitric oxide, formed during 100 seconds of exposure when the light was cut off. Average extermination periods for paramecia in 1% suspensions of cane sugar, urea, alanine, leucine, gelatin, and peptone were determined, and for the last three were 215, 220 and 300 seconds respectively, while the first three gave results only slightly higher than those for water. Glutamic, aminobenzoic and aspartic acids were each toxic for the organisms and could not be used directly. Tyrosine, though very sparingly soluble in water, in saturated solution was decidedly protective and lengthened the extermination period to 180 seconds. Alkaline solutions were toxic. In order to test these toxic solutions the paramecia were placed in a flat watch glass, covered with a card having a circular hole into which a quartz beaker containing the test solution fitted. Solutions cystine and tyrosine were made by adding a slight amount of caustic soda. The results showed that solutions of aminobenzoic acid, cystine, tyrosine and leucine detoxicated ultra violet rays which pass through them. The protective action of tyrosine in alkali solution was especially marked; 1% tyrosine in 0.2% caustic soda perfectly screened the organisms during 40 minutes of exposure. The action of leucine, which does not exhibit selective absorption for ultra violet light, was attributed to a chemical change in the leucine solution induced by exposure to the light yielding a substance having an increased power of absorbing ultra violet rays. This view is supported by the fact of a change of color in a leucine solution thus exposed. The results of this study "are in harmony with the view that the susceptibility of protoplasm to ultra violet light is conditioned by the selective absorption of the toxic rays by the aromatic amino acid radicals of the proteins."

Photographic Registration of Ultra Violet Spectra.

An apparatus for the quantitative photographic registration of ultra violet spectra has been devised by *Lankshear* (Chem. abs., 1917, 3133; Proc. Manchester Lit. Phil. Soc., 1915, 1-4). The optical part proper consists of two identical trains of quartz reflecting prisms and condensers focusing comparable beams from the same light source upon the slit of the quartz-prism spectrograph. In the path of one beam is placed the absorption vessel, in the path of the other a sector for quantitatively altering the comparison intensity. The sector is the novel feature, being designed to avoid intermittent illumination and the consequent photographic error. Instead of slots out near the periphery, as is usual, there is a single semi-circular hole the diameter of which passes through the center of the wheel. A disk having a corresponding hole in it can be rotated on the face of the sector wheel, thus altering the aperture of the sector. The latter is graduated logarithmically, because the measured quality is log (1/1°). In view of possible slight defects in the quartz condenser the sector can be rotated if necessary, either by hand or by clockwork. Details are given as to centering and adjustment. It is pointed out that the central sector acts by cutting down the beam, which nevertheless falls continuously on the photographic plate. While with the Hilger instrument the greatest length of fluid which can be used is 5 centimeters, with the new apparatus a Baly tube can be used, and with one solution the extinction coefficient over a wide range of the spectrum determined. Also, since the image is focused on the slit instead of on the object glass, an increased amount of light is obtained in the spectrograph.

Notes on Ultra Violet Lamps.

The mercury arc was first studied by Arons in 1892 and was developed commercially by Cooper-Hewitt in 1902. According to *Child* (Electrical Arc, VanNostrand, 1913, 87) the advantages claimed for the mercury arc as a source of light are that the rays are not emitted from a small space as in the ordinary arc, but they extend along a tube which is usually six or more inches in length and that the operation of lamp is very simple; there being no necessity for adjustment of the electrodes and no renewals. As long as the vacuum of the tube is intact the lamp is in adjustment for operation. The fact that mercury vapor loses its conductivity very rapidly when the lamp is extinguished makes the use of the alternating current impossible, a direct current being necessary for satisfactory operation.

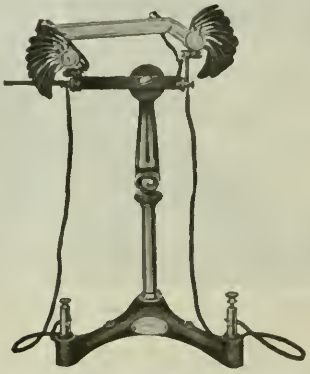

Fig. 6—Heraeus quartz mercury vapor lamp for direct current. (Note copper "fins" for heat radiation.)
(Courtesy Hanovia Chem. Mfg. Co., Newark, N. J.)

The Heraeus quartz mercury vapor lamp (see Fig. 6) consists of three essential parts: the quartz tube through which the arc plays, an anode receptacle and a cathode receptacle. The current is carried to the lamp through nickel rods ground into the side tubes of the electrode receptacles, the joints being sealed with mercury. The mercury chambers are kept at a somewhat lower temperature than the remaining portion of the lamp by means of fins made of copper, which serve to radiate heat rapidly. The quartz lamp proper is supported upon a stand and after being put in operation by tilting may be burned either in a horizontal or vertical position. The lamp is made to burn on either 110 or 220 volt circuits and it is claimed that the efficiency is substantially the same in either case. Figure 8 is a photograph of the spectrum of the Heraeus lamp, which gives an idea of the richness of the rays in the ultra violet region; this is shown by the length of the spectrum falling to the left of line 3900 Angstrom units, which portion of the spectrum is not visible to the eye.

The Heraeus vapor lamp is also made for alternating current, the difference in construction being that for this current it is necessary that there be two positive electrodes in place of the one ordinarily used for direct current. (See *Fig. 7.*)

A mercury vapor lamp manufactured by the General Electric Co., as described by Child (Electrical Arc, Van Nostrand, 1915), consists of a carbon anode and a mercury cathode. A fine carbon filament runs through the lamp and dips into an iron cup which floats on mercury in the bottom of a tube. As soon as the current is started the cup is drawn down by means of a solenoid, thus forming an arc at the bottom of the carbon filament, and as this is more resistant to the current than mercury vapor the arc rapidly extends through the whole length of the tube.

Sealing Wires in Quartz.

A method of sealing wires of molybdenum and molybdenum alloys gas-tight in quartz glass is proposed by Podszus (Chem. Abs. 1918, German Pat. 293,963, Mar. 15, 1914). A flux consisting of about ten parts silica, one part alumina and one part boric acid is suggested. The content of silica in the flux is increased towards the body of the quartz. The union is stated to be improved by the presence of a small amount of oxide on the surface of the metal or alloy, due to the solvent action of the flux for such oxides. For this purpose two parts of orthoclase may be added to the flux immediately surrounding the metal wire. Alkali earths produce the same results.

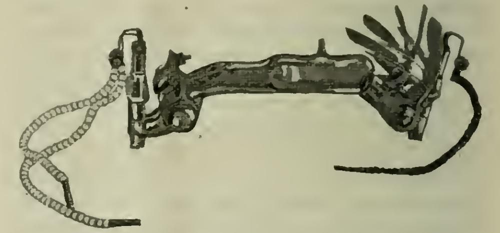

Fig. 7—Heraeus quartz mercury vapor lamp for alternating current.
(Courtesy Hanovia Chem. Mfg. Co., Newark, N. J.)

Luckiesh (*Met.* & Chem. Eng. 1918, *232*) refers to various sources of ultra violet light and discusses their uses. The ideal source of light is one which will give as near as possible a continuous spectrum through the desired region. But up to the present such a source has not been developed except within somewhat narrow limits. The sun emits a fairly continuous spectrum as low as $295\ \mu\mu$, but there are some dark lines due to selective absorption. The mercury arc has advantages of steadiness, but has some large gaps in the spectrum, and the ultra violet energy decreases in the case of old lamps. Some old quartz mercury arcs have been found only half as effective as they were when new. The ordinary carbon arc emits a considerable quantity of ultra violet rays in the near and middle regions. The magnetite arc has a positive pole of copper and a negative pole consisting of a sheet steel tube packed with a fine powder consisting principally of oxides of iron (magnetite), titanium, and chromium. This arc is fairly rich in ultra violet rays.

Rating of Different Sources.

Measured from the standpoint of total ultra violet energy per unit of visual intensity of illumination, Bell (Elec. World, Apr. 13, 1912) ranks these sources in the following order: magnetite arc, old mercury arc, new mercury arc, and carbon arc, the last two being about equal on this basis and more than twice as rich in ultra violet rays as the first two. This basis is of interest in lighting, but it should be noted that, in general, the ultra violet output per watt of energy input is generally of interest.

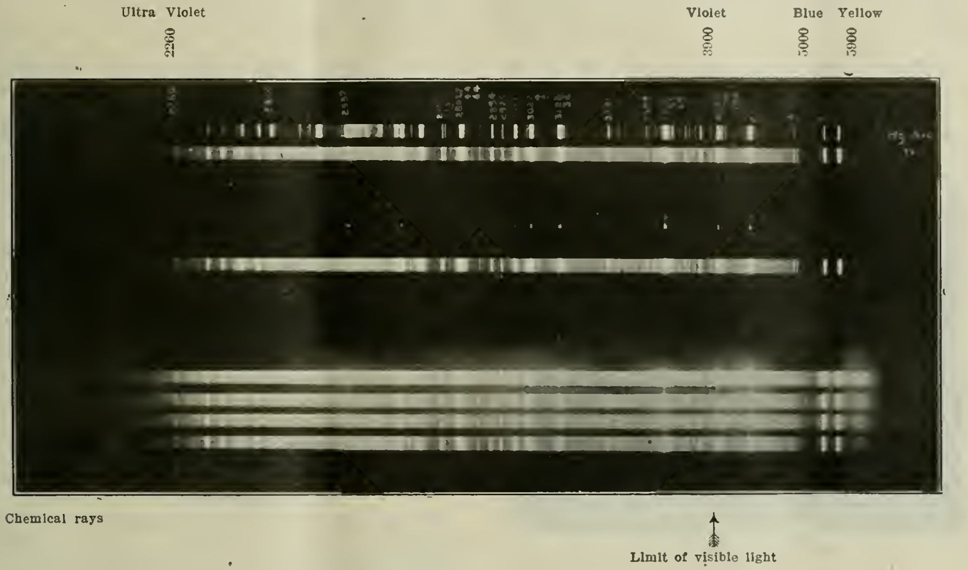

Fig. 8—Photograph of spectrum of Heraeus direct current mercury vapor lamp.

Lyman has shown that the mercury arc emits a strong line near 185 $\mu\mu$ which will be very effective, in some reactions, with a short air-path, but only feeble with a long air-path owing to the absorption by the air. This indicates that, when dealing with radiation of such short wave-lengths, very different results may be obtained with the same source, depending upon the distance of the reaction from the source.

The Flame Arc.

The flame arc has potential possibilities as a source of ultra violet rays owing to the diversity of materials with which the carbons may be impregnated. It has been found that the feebly luminous flame of the ordinary carbon arc is the source of much of the short-wave ultra violet energy emitted. The white-flame arc of high amperage, in proportion to the energy input, is the most efficient commercial source of near and middle ultra violet energy available at present. It radiates energy quite extensively in the near and middle regions. Obviously the blue flame arc emits ultra violet energy very strongly.

Construction of Iron Arc Apparatus.

It is a simple matter to construct an arc which will emit ultra violet energy strongly, provided hand-control is satisfactory. An iron rod and a carbon rod may be employed successfully for the two poles; however, two iron rods may answer the purpose very well. These poles may be kept cool effectively by means of heavy brass or copper sleeves which may be moved along the iron rods as the latter are consumed. A particularly successful iron arc of this type can be made very readily. The upper pole, which is negative, may be an iron rod about ¼-in. in diameter. This is surrounded by a movable but well-fitted solid sleeve of copper about one inch in diameter. The lower pole may be an iron rod about ½-inch in diameter with the end in the form of a shallow dish. One pole should be adjustable vertically. In preparing the arc a bead of molten metal is developed in the dished end of the lower electrode, the latter becoming oxidized, which apparently decreases the rapidity of deterioration. The upper electrode is well cooled and the arc is maintained very steadily between the molten bead of iron and the upper solid electrode. Luckiesch has had such an arc operate at a rather high current density for thirty minutes without any adjustment. The dimensions may be increased to meet the requirements. It is not a difficult matter to make various simple arcs which are quite satisfactory for a great deal of work.

Sparking Apparatus.

For many purposes, according to Luckiesch, the spark between metallic electrodes is very satisfactory but, in general, sparks can not compete with arcs in quantity of ultra violet energy emitted. Various forms of spark gaps have been employed depending upon the requirements; usually steadiness of position of the spark and shadows of the poles are the factors which determine the shape of the gap. A short spark obtained from a transformer may be satisfactory or it may be fattened by using a condenser. A high frequency spark may sometimes be desirable. The kind of spark obtained depends upon dimensions and electrical relations and obviously these may be widely varied. The metals commonly employed for the poles of spark gaps are aluminum, zinc, iron, copper, and cadmium, although any other may be satisfactory, depending upon its spectrum and upon the specific requirements.

Vacuum Tubes.

The spectra of electrically excited gases confined at low pressures in transparent tubes have been extensively studied, but Luckiesch states that such vacuum discharge tubes have found little or no use in industrial processes. They have provided sources of extreme value in some investigations. The spectrum of hydrogen under these conditions exhibits many lines and bands in the Schumann region. These tubes are usually of the capillary type and contain the gas at low pressures of the order of magnitude of one mm. of mercury. In order to be useful in the extreme short-wave region, they must be provided with a fluorite window.

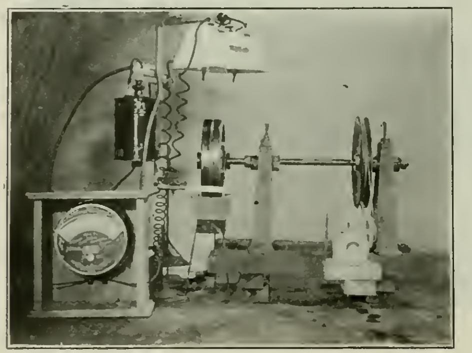

Fig. 15—Type of laboratory apparatus for exposure of oils to ultra violet rays.

Extraordinary Variations in Wave Lengths.

In discussing the subject of ultra violet light and the narrow limits of the length of the light waves which are active in sterilization and in aiding chemical reaction, it is interesting to make a comparison with the length of other waves with which we are familiar, viz.,—the colors of the spectrum, heat waves, sound waves, and electric waves.

The color spectrum ranges from .00065 mm. for red at one end of the visible spectrum to .00040 mm. for violet and .00012 mm. for extreme ultra violet, which is the lower limit of the metallic arc. The lower limit of the mercury spectrum is .00022 mm. while the wave length most efficient for sterilization is .00028 mm.

Wave lengths shorter than .00036 are scarcely visible to the human eye. The upper limit of the infra red rays as given off by a welsbach lamp is .60 mm. The wave length of heat waves at 0°C. is .0107 mm., a shrill whistle sends out waves 13 mm. long, middle C on a piano has a wave length of 1300 m., wireless telegraphic waves are in the neighborhood of 30500 mm., while the ordinary 60 cycle alternating field current has a wave length of 4,990 million mm. or 3,100 miles.

In order to illustrate these figures and put them in a form where we can get an idea of the comparative values of each, let us multiply them by the factor 10,000, which will give us in round numbers 1 mm. for extreme ultra violet, or, say the thickness of an ordinary pin, violet would then be twice the width of the pin head, red would be a quarter the length of the pin, heat waves at 0°C temperature would have a length of 4¼ inches, a shrill whistle would have a wave length of nearly one and one-half city blocks, while middle C on the piano would give off waves eight miles long. The shortest wireless telegraph wave would then be 190 miles long, or the distance from New York City to Albany, while the 60 cycle a.c. field current would be 31 million miles or one-third the distance from the earth to the sun. The limiting values of ultra violet wave lengths and their place in the domain of elastic fluid undulations is thus strikingly illustrated.

Dehydration.

The influence of light on the evolution of water of hydration from salts has been observed by *Beutel*, (Oesterr. Chem. Ztg. 19, 123-4; through Chem. Zentr. 1916, II, 638. Chem. Abs. 1918, 249), who observed that efflorescent spots appearing on crystals of chrome alum and of cobalt magnesium sulphate increased very rapidly on exposure to light In ultra violet light from a mercury arc the decrease in weight was nearly twice as great as in the dark.

Fig. 15 illustrates laboratory apparatus used in subjecting oils to the action of ultra violet light. A grooved pulley driven by a worm gear and motor connections causes a flat pulley to revolve in a pan of oil supported on a tripod. The ultra violet lamp is placed directly over the flat pulley and the oil is exposed thereto as a thin film. A spatula placed against the face of the pulley removes the insolated oil. On the left is shown a voltmeter and immediately above it, a rheostat controlling the flow of current to the lamp.

(To be continued in the April issue.)

Hawkes Now a General Chemical Co. Director.

A. W. Hawkes has been elected a director of the General Chemical Co. of New York to succeed John M. Goetchius, who has resigned to enter Government service.

The Eagle Paint & Varnish Co, Pittsburg, Pa., has just completed alterations and improvements to its plant to provide for increased capacity.

INORGANIC CHEMICAL SYNONYMS

A Novel Work of Reference for Student and Chemist

By

ELTON R. DARLING*

Although Intended Primarily for the Student, It Is Believed that the Following Compilation of the Various Terms Employed to Designate Inorganic Chemicals Used in the Industries Will Prove a Convenience to the Experienced Chemist. The Writer Claims No Originality for the Synonyms, but Only the Bibliographical Research of the Material at Hand.

Part IV Will Appear in the Next Issue.

PART III

Cadmium. 112.4.

It has a specific gravity of 8.6, a fusing point of 228°C., melts at 321° C., boils at 778° C. and has a valency of two.

Cadmium was discovered at about the same time in 1817 by two independent workers under varied conditions. Strohmeyer, one of the two to whom the credit for its discovery was given, while engaged in some work on a sample of zinc carbonate, obtained from the zinc mines at Salzgitter, noticed that the oxide contained a yellow color, yet was free from iron. In 1818 he published a full account of his work and also named the element.

Hermann, at the same time, made an examination of a sample of zinc oxide which was used for pharmaceutical purposes and which had been rejected because, upon treatment with acid, it gave a yellow solution. He announced a new metal.

Shortly after Strohmeyer and Hermann made known their work on the new element, Meissner and Karster confirmed their report.

- Cadmium Chloride. 219.35
  - *Chloride of Cadmimum*
  - *Muriate of Cadmimum*
  - *Cadmic Chloride*
  - *Butter of Cadmimum*
- Cadmium Oxide. 128.4
  - *Cadmii Oxidum*
  - *Cadmic Oxide*
  - *Protoxide of Cadmimum*
- Cadmium Sulfate. 280.53
  - *Cadmii Sulfas*
  - *Sulfate of Cadmium*
  - *Vitriolate of Cadmium*
  - *Cadmic Sulfate*
- Cadmium Sulfide. 144.47
  - *Cadmii Sulfidum*
  - *Cadmic Sulfic*
  - *Cadmium Yellow*
  - *Jaune Brillant*
  - *Greenockite* (native)

Calcium. 40.07.

Although metallic calcium was not prepared until 1808 by Davy, its compounds were used by the ancients.

The use of lime in the preparation of mortar for building belongs to the pages of unknown history. Dioscorides and Pliny, in their writings, give a very complete description of the process for lime-burning and slaking.

This metal has a specific gravity of 1.545, a melting point of 800° C. and sublimes a little above this point. It has a valence of two.

- Calcium Acetate. 176.13
  - *Calcii Acetas*
  - *Diacetate of Lime*
  - *Pyrolignite of Lime*
  - *Vinegar Salts*
  - *Brown Acetate*
  - *Grey Acetate*
- Calcium Carbonate. 100.07
  - *Calcii Carbonas Precipitatus*
  - *Precipitated Chalk*
  - *Spanish White*
  - *Carbonate of Lime*
  - *Spanish Whiting*
  - *Whiting*
  - *Paris White*
  - *English White*
  - *Limestone (native)*
  - *Marble (native)*
  - *Calcite (native)*
  - *Aragonite (native)*
- Calcium Chloride. 110.99
  - *Calcii Chloridum*
  - *Chloride of Calcium*
  - *Muriate of Lime*
  - *Muriate of Calcium*
- Calcium Fluoride. 78.07
  - *Calcii Fluoridum*
  - *Fluor Spar*
- Calcium Hydroxide. 74.09
  - *Calx Extincta*
  - *Aqua Calcis*
  - *Calcium Hydrate*
  - *Slack Lime*
  - *Calcic Hydrate*
  - *Lime Water*
  - *Solution of Lime*
  - *Caustic Lime*

---

*All rights of publication in book form reserved by the author. Research Textile Chemist, 251 Clifton Place, Brooklyn, N. Y.

Calcium Hypochlorite. 215.05
Calx Chlorinata
Calx Chlorata
Chlorinated Lime
Bleaching Powder
Chloride of Lime (improperly called)

Calcium Oxide. 56.07
Calx
Calx Uiva
Caustic Lime
Quick Lime
Lime
Calcic Oxide
Burned Lime
Unslaked Lime

Calcium Sulfate. 172.17
Calcii Sulfas
Pearl Hardener
Gypsum (native)
Silenite (native)
Alabaster (native)

Dried Calcium Sulfate. 136.14
Calcii Sulfas Exsiccatus
Anhydrous Calcium Sulfate
Plaster of Paris
Dried Gypsum
Calcined Gypsum
Bihydrate of Lime
Calcined Plaster
Vitriolate of Lime
Vitriolate of Calcium

Calcium Phosfate. 310.29
Calcii Phosfas
Phosfate of Lime
Bone Ash (crude)
Bone Earth (crude)
Tricalcic Phosfate

Chromium. 52.

It has a specific gravity of 6.92, a melting point of 1505° C. and a boiling point of 2200° C.

A peculiar feature of chromium is its atomicity, which is diatomic, tetratomic, and hexatomic. It has also shown octatomicity.

Our first notice regarding chromium was contained in a private communication of Lehmann in 1762. For the benefit of a friend he described a new mineral which came from Siberia. Nothing definite was done regarding its composition until twenty-seven years later, when Vauquelin and Macquart investigated the mineral. Their results were not satisfactory, but they concluded that it contained a large quantity of lead and oxygen. In 1797 Macquart, not feeling satisfied with the results he had previously obtained, carried out a new investigation. He found that the lead was combined with the oxide of a new metal. To this was given the name Chromium. The mineral from which the study was made is now called Crocoisite.

Chromium Dichloride. 122.92.
Chromii Dichloridum
Chromous Chloride
Muriate of Chrome
Protochloride of Chrome
Butter of Chrome

Chromous Oxide. 84.
Protoxide of Chromium
Dioxide of Chromium
Green Oxide of Chrome
Chrome Green

Chromium Oxide. 100.
Chromii Oxidum
Chromic Oxide
Chromium Sesquioxide

Chromium Trioxide. 152.
Chromii Trioxidum
Acidum Chromicum
Chromic Acid
Chromic Anhydride
Anhydrous Chromic Acid

Chromium Sulfate. 482.29.
Chromii Sulfas
Vitrolate of Chromium
Wool Mordant.

Cobalt. 58.97.

Cobalt has a specific gravity of 8.72 and a melting point of 1490° C. The valency in the cobaltous compounds is two, and four in the cobaltic.

The name cobalt carries us back to the days of Paracelsus and "Basil Valentine." In those days it was not used to denote the element, but meant instead "false ore."

In 1733 Brandt came to the conclusion that the blue color of glass was caused by a peculiar metal in the mineral used in its manufacture. He gave it the name of "kobalt."

Cobalt Chloride. 129.89.
Cobaltum Chloridum
Muriate of Cobalt
Hydrochloride of Cobalt
Dichloride of Cobalt
Cobaltous Chloride
Butter of Cobalt

Cobalt Oxide. 74.97.
Cobaltum Oxidum
Cobalt Protoxide
Oxide of Cobalt
Cobalt Black
Gray Oxide of Cobalt
Black Oxide of Cobalt
Cobalt Monoxide
Cobaltous Oxide
Asbolite (Native)

Copper. 63.57.

It has a specific gravity of 8.9, melts at 1065° C. and boils at 2310° C. It is diatomic in valency.

Copper was probably the first metal to be used by mankind. The reason for this was that it occurred in the native condition, and did not require any further treatment.

Copper Chloride. 170.52.
 Cupri Chloridum
 Cupric Chloride
 Subchloride of Copper
 Muriate of Copper

Cupric Oxide. 79.57.
 Cupri Oxidum
 Black Oxide of Copper
 Copper Monoxide
 Protoxide of Copper
 Melaconite. (Native)

Copper Oxide. 143.14.
 Cuprous Oxide
 Red Oxide of Copper
 Dinoxide of Copper

Copper Sulfate. 249.72.
 Cupri Sulfas
 Sulfate of Copper
 Copper Deutosulfate
 Blue Coppras
 Blue Stone
 Blue Vitriol
 Roman Vitriol
 Salzburg Vitriol

Iron. 55.84.

It is also known as Ferrum.

Iron has a specific gravity of 7.8, melts at 1505° C., and boils at 2450° C.

It has a valency of two when the salts are ferrous, and four when ferric.

Iron is another of those few elements, the history of which began with the history of mankind.

Ferrous Carbonate 133.86.
 Ferri Carbonas
 Ferri Subcarbonas
 Carbonate of Iron
 Protocarbonate of Iron

Ferric Chloride. 270.32.
 Ferri Chloridum
 Ferri Perchloridum
 Ferri Sesquichloridum
 Iron Chloride
 Sesquichloride of Iron
 Perchloride of Iron
 Trichloride of Iron
 Muriate of Iron

Ferric Oxide. 159.68.
 Ferri Oxidum
 Ferri Sesquioxidum
 Ferri Rubigo
 Rubigo
 Ferri Peroxidum
 Ferri Oxidum Rubrum
 Peroxide of Iron
 Red Oxide of Iron
 Iron Rust
 Sesquioxyde of Iron
 Crocus Ferri
 Crocus Martis
 Ferrugo
 Polishing Crocus
 Jeweler's Rouge
 Venetian Red
 Stone Red
 Indian Red
 Purple Oxide
 Scarlet Red

Ferrous Oxide. 71.84.
 Ferri Oxidum
 Monoxide of Iron
 Iron Monoxide
 Suboxide of Iron
 Iron Suboxide

Ferrous Sulfate. 278.02.
 Ferri Sulfas
 Ferrum Vitriolatum
 Protosulfate of Iron
 Sulfate of Iron
 Coppras
 Green Vitrol
 Sal Chalybis
 Salts of Steel
 Vitriolate. of Iron
 Iron Vitrol

Ferric Sulfate. 562.03.
 Ferri Tersulfas
 Persulfate of Iron
 Sesquisulfate of Iron
 Tersulfate of Iron.

Analysis of the Chemist—Qualitative and Quantitative

By the Youth

Our neighbor, the *Canadian Chemical Journal*, is responsible for the publication of the following extremely amusing bit of satire, which we herewith reproduce in full:

Ottawa, the Ides of March.

A chemist is a thin film of matter, one atom deep, which clings to industry like a scum for support. He travels in more disguises than any Sherlock ever dreamed of and gathers infinitely less booty along the way. His temerity is such that he would think twice before holding up a fly—for more salary. Every chemist is the best chemist that ever carried rotten results to four places of decimals. His sense of co-operation with any other chemist is less than that of an exploding powder plant. A "professional chemist" is a misnomer. There is no such profession. Ask the first real professional man you meet and he will tell you.

The only things in a chemist's world are other things. If you introduced him to a man getting $200 a month he would probably blush, lift his hat, and how. He blows his own horn with the same sense of probable effect as a man learning to play a clarionet. He feels in his soul that it is just barely possible that the public needs education to appreciate him so he spends his spare time telling his closest friend—the stenographer—what a "basic industry" is. For him all the real salaries are in Peru.

Being a true descendant of one Dalton he still imagines himself to be a "perfectly elastic sphere," without pockets, or hooks of attachment of any kind visible or invisible. Having less general intelligence than the average potato he refuses to sprout. Some abnormal specimens have been known to sprout, but it never ran to two generations and is by no means contagious. He jumps from one "job" to any other with the alacrity of a cat and with the same "green field far away" look in his eye. The words, "position," "manager," "executive," were left out of his dictionary.

Having attended lectures and mopped up experience on all subjects at great price—except that variety given gratis by barbers and street car conductors' unions—he feels more than confident that he can pass the buck up to the whole world all alone. Should he by any chance fail to sustain the 20 per cent. dividend of his firm he has a most peculiar sense of dying game in the attempt. He has the same cause as the early Christians for desiring wealth in the future world.

His ancestors are the most notorious ancestors on record. He is in direct line with all the thugs of the Middle Ages. With such a handicap it is no wonder that the leading grocers refuse him the chance of leaving his card, even today, while the doctors, lawyers, and dentists, turn up their noses in utter scorn, crying "Unclean!"

Only such things as plagues and epoch making wars have a ghost of a chance of blowing the debris and junk on his head. Sometimes by reading carefully between the lines of his own trade journals he thinks he sees emancipation for him. Being thus encouraged by his cosmopolitan view he again approaches the stenographer, whom he finds has a date on with the lawyer—a future premier. So after all he guesses the war might not stop if he slept in the morning. They would probably go after each other with stones anyway. Cogitating thusly he deftly lowers the trap door over his head once again. Relatively speaking, "going down."

T. N. T. Plant to be Erected.

Announcement has been made that work will be started at once on the erection of one of the largest plants in the United States for the manufacture of T. N. T., to be located at Hercules, Cal. The plant will form an addition to the works of the Hercules Powder Co. Details as to the plant's capacity are not as yet forthcoming.

NEW PUBLICATIONS

"Finding and Stopping Waste in Modern Boiler Rooms."

By Engineers of the Harrison Safety Boiler Works, Philadelphia, Pa.; cloth; 9 inches by 7 inches; pages 276; 213 illustrations; $1.00.

The saving of coal is the purpose of this practical handbook, which is addressed to power plant owners, managers, engineers and fireman. The preface states that such statements, tables, charts, etc., have been selected as were supported by experiments and tests, references being given wherever possible to the original authorities. The latter include many well-known engineers and writers in technical periodicals, also authors of papers before engineering societies, while the excellent bulletins on the utilization of fuel issued during recent years by the United States Bureau of Mines have been freely drawn upon. Pains have been taken to compare statements and to check each source of information against others.

The work is divided into five sections, the first of which is about "Fuels," under which are considered the coals of the United States and their classifications, size of coal, coal sampling, proximate analysis, ultimate analysis, heating value of coal, ash and clinker, value of coal for steaming purposes, purchase of coal under specification, washing of coal, storage and weathering of coal, coal measurement, oil fuels and gaseous fuels.

The second section is on "Combustion," taking up the chemistry of combustion, air theoretically required, grates and grate surface, hand firing methods, thickness of fire, mechanical stokers and their operation, furnace temperature, furnace gases, clinker, draft, flue and stack proportions, draft required by stokers, mechanical stokers, draft gages, dampers, flue gas temperatures, flue gas analysis, Co_2 recorders, what CO_2 indicates, what CO indicates, air requirements and supply, preventing excess air, smoke and smoke prevention, burning oil fuel, burning gaseous fuels, and burning powdered coal.

The third section treats of "Heat Absorption," including heat transmission by conduction, convection and radiation, heat transfer from a fluid in a channel, heat transfer in economizers, air heaters and superheaters, improving heat absorption, relation between heating surface and boiler capacity, boiler setting, refractories and fire brick, soot, scale, softening feed water, and feed water heating.

The fourth section on "Boiler Efficiency and Boiler Testing" covers heat balance, heat absorbed by boiler, heat losses due to moisture in the coal, hydrogen, chimney gases, CO, combustible in the ash, mosture in the air, and unaccounted for loss, efficiencies, efficiencies with different coals, boiler capacity and efficiency, and boiler trials.

The fifth section on "Boiler Plant Proportioning and Management" discusses various arrangements of auxiliaries with regard to their effect upon feed heating, and also describes the Polakov functional system of boiler room management.

The book has been compiled by George H. Gibson, Member American Society Mechanical Engineers, assisted by Percy S. Lyon, now Captain of Coast Artillery. The proofs were read by Mr. Henry Kreisinger, who conducted for the U. S. Bureau of Mines many of the investigations quoted in the text.

New Publications of the U. S. Bureau of Standards.

Scientific Paper 313: Specific Heat of Liquid Ammonia.

The Bureau's investigations of refrigeration constants have included the careful study of the thermal properties of ammonia. Such calorimetric data are of primary importance in the computations of tables adapted to the needs of the refrigeration engineer. The determination of the specific heat of liquid ammonia has been attended with considerable difficulty, but the progress in artificial refrigeration has made it a matter of great importance. The research gives the specific heat through the range —45° to +45° C. within one part in a thousand. The results are tabulated for convenience in use.

Scientific Paper 314: Latent Heat of Pressure Variation of Liquid Ammonia.

This paper describes the research of the amount of heat needed to neutralize the temperature change of a substanc with a definite change of pressure. This change is sufficiently large to be taken into account in actual calorimetry. This constant was determined by three independent methods with satisfactory concordance of results.

Scientific Paper 315:Latent Heat of Vaporization of Ammonia.

This paper gives detailed description of the calorimeter designed to determine the latent heat of vaporization of ammonia. This important refrigeration constant was determined through the temperature interval —42° to +52° C. At 0° the latent heat is 301.8 calories per gram. The results of 34 separate determinations agree with the mean within one part in one thousand.

Société de Chimie Industrielle.

Paris le 25 Février, 1918.

Monsieur le Directeur de Chemical Engineer.

Nous avons l'honneur et le plaisir de vous annoncer la constitution en France, d'une "Société de Chimie Industrielle."

Fondée pour établir une liasion permanente entre la Science et l'Industrie, cette association groupe déjà les notablitiés des diverses régions de notre Pays. Son Conseil d'administration comprend les personnalités les plus éminentes de l'Industrie. Le Comité de rédaction de ses publications est composé des noms les plus marquants de la Science. C'est en quelque sorte l'alliance de toutes les forces vives de France décidées à agir en commun, pour:

1°. Contribuer â l'expansion de l'Industrie chimique dans tous ses domaines;

2°. Grouper tous les chefs d'industrie: Professeurs, Ingénieurs, Chimistes, Constructeurs, etc., qui y sont intéressés;

3°. Contribuer aus progrès de la Chimie Industrielle tant au point de vue économique qu'au point de vue scientifique.

Une Revue technique constituera l'organe officiel de notre groupement et servia de trait d'union entre tous nos membres. Destinée à les entir au courant, non seulement des travaux re nos compatriotes, mais encore des nouvelles recherches scientifiques entreprises dans les différents Pays, elle s'attachera à élargir de plus en plus le domaine des inteventions pratiques de la Chimie.

Avant la guerre, nos deux nations ressentaient ensemble tout le poids des efforts de la Chimie allemande et de l'envahissement de ses porduits. Elles luttent en ce moment pour la même cause: la défense de l'humanité et l'émancipation du Monde. C'est un devoir pour elles, maintenant qu'elles se sont libérées de l'étrein te si lourde de pensar à l'avenir et de le préparer.

Depuis de longues années et en particular ces temps derniers, nos rapports nous ont apris à nous mieux connaitre et à nous apprécier davantage. Cet accord confiant et parfait qui préside aux relations cordiales que nos nations respectives entre tiennent doit être continué aprés la guerre, si nous voulons que la victoire porte ses fruits. Notre triomphe sur les champs de bataille doit s'accompagner d'une forte organization économique interalliée, afin de déjouer les nouveaux plans de domination commerciale et industrielle que viennent d'élaborer les empires centraux.

A l'heure ou dans tous les Pays de l'entente, les hommes soucieux d'un avenir heureux fécond, songent à ces lendemains d'efforts communs et d'inébrenlable amité, il est bon que les grandes associations multiplient entre les divers peuples aliés, les moyens de pénéeration réciproque, les échanges de pensées, de sympathie et de vues pour l'avenir.

La diffusion des publications scientifiques & techniques peut aider, dans une large mesure, à affermir et à accroitre les sentiments qui unisent nos deux patries. Nous la faciliterons, de notre côtée, avec toute l'ardeur de nos aspirations.

Nous nous permettons de faire appel à votre sympathie et venons vous demander dans quelles conditions vous seriez décidés à titre de propagande, à nous envoyer, pour la bibliothéque très importante que nous constituons, les diverses publications susceptibles de nous intéresser, notamment:

"The Chemical Engineer."

Nous pourrions, peut-être, faire un échange de nos publications. Mais, comme notre Revue ne paraitra qu'en Avril porchain nous vous serions très reconnaissants de nous faire "don," pour notre bibliothèque, des numéros de l'année 1917.

Le Sechétaire-Général,
JEAN GERARD.

Matheson Now Heads National Aniline.

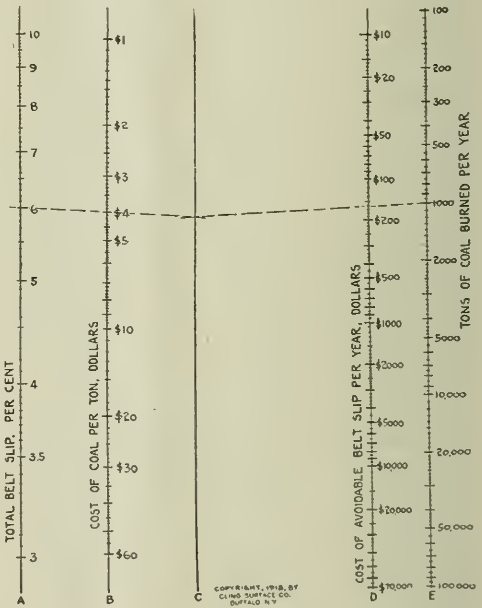
As a result of the reorganization of the National Aniline & Chemical Co., J. L. Schoellkopf and C. P. Hugo Schoellkopf, former president and third vice-president respectively, have withdrawn from its active management, but will continue as directors and stock-holders. The new president is William J. Matheson, a director of the General Chemical Co., while Dr. L. C. Jones of the Solvay Process Co. is vice-president.

The Cost in Coal of Avoidable Belt Slip.

Avoidable losses are the ones to stop, always, especially if they can be stopped at small expense.

Never before have we understood the stategic and money value of coal as thoroughly as we do now. Never before has it been so necessary for us to save, even though considerable money must be spent in order to effect the saving.

One of the very simplest losses to overcome, however, and at small expense, is belt slip, and since belts are used to so great an extent it will pay to look into the matter with more thoroughness than has been given it in the past. To show the extent of the loss of money through slipping of the main belt alone, a chart, supplied us through the courtesy of the Cling-Surface Company, Buffalo, N. Y., is shown herewith, upon which this is easily ascertained. By glancing up and down column "D" of this chart it is evident that the "Cost of Avoidable Belt Slip per Year in Dollars" may vary all the way from the smallest sums into the thousands of dollars.



Where the power in the first place is generated by a steam engine and is then transmitted to a generator or to the main shaft through a main belt, it is evident that the "entire coal pile" passes through that in the form of energy, literally speaking. If the belt slips, which it should not do, a certain portion of the coal pile does not "get through," but is lost into the atmosphere in the form of waste heat.

A main belt is merely a "link" connecting the engine with the generator or with the machines themselves. In fact every belt that transmits power is a connecting link and the efficiency of that link depends largely upon the freedom from slippage and the avoidance of strain on the shafts.

A Power Plant Is a Train of Links.

For the moment it might be well to dwell upon this thought, as it is seldom looked at in just this light.

We have for the first link the coal on the grates, which only perfect combustion can turn into maximum heat; next the boiler shell and tubes—they must be clean to bring the heat link to the steam link; next the steam line from boiler to engine or turbine—large enough and well insulated; then the engine or turbine link which joins heat energy and mechanical energy—only careful design, proper valve setting and much care minimize losses here.

Then, where power is distributed solely through belts and pulleys, the belts, pulleys and shafts or electrical cables to the final motors and belts are the connecting links up to the very machines themselves.

If the efficiency of every link is maintained at its highest point, the power end of the plant is beyond criticism. The overall efficiency will then be very high. But if the efficiency of every link is low or indifferent, the overall efficiency of the power end will be distressingly low.

Mere Matter of Detail?

Many of us talk glibly about efficiency as though it could be acquired over night. Thus, one man has stated that "Efficiency is a mere matter of detail." His definition is all right, but detail is not "mere matter!"

Belt Slip Not "Mere Matter," Either.

For these various reasons, therefore, it is plain that power transmission through belting is a "detail" on which we should "plug" until all avoidable slip is eliminated. It is especially important, as stated before, where all the power passes through a single main drive belt. Each per cent of slip in such a belt represents a loss of one per cent of the coal pile.

Roughly, two per cent of the potential power in the driving pulley of the engine is represented by "belt creep." Its loss is unavoidable because of the elasticity of the belt. This has been recognized and provided for in the chart, so the reader can go ahead and connect known values, while the intersection with column "D" gives the avoidable money loss.

How to Use Chart.

Simply zig-zag across the chart twice with a straight-edge, as shown by the dotted lines, and the money loss is immediately found. Thus, if the total belt slip is 6 per cent. (column A) and the cost of coal per ton is \$4.00 (column B), run a straight line through those two points and locate the intersection with column "C." Then from that point of intersection run over to the tons of coal burned per year (which in this instance has been stated as 1,000 tons) and the cost of avoidable belt slip per year is shown by column "D" as being \$160.00.

Yearly loss due to belt slip is often considerably greater than \$160.00, for it must be remembered that this chart applies only to ONE belt—the main belt. If all of the distributing or secondary belts slip equally as much the yearly loss is double, triple or even four times as much as \$160.00.

"Total Belt Slip Per Cent."

To give a clear idea as to the meaning of "Total Belt Slip Per Cent." let us take an example. You find by means of a revolution counter that a given driven pulley is rotating only 940 times per minute. You figure that without slip it should rotate 1,000 times per minute; 60 revolutions per minute, therefore, are absolutely lost. Dividing this 60 by the r. m. p. that pulley SHOULD make you get 0.060 or 6 per cent. which is the "Total Belt Slip." After having made this determination, now it is a simple matter to apply it to the chart, as has been done, and determine the money loss per year due to such slip.

Furthermore, belts which do not slip do not require tension and can be run easy or slack—every belt thus relieved of its tension reduces by that much the total plant friction load and this means also a longer-lived belt, cool bearings, less oil used, less time of men and machines lost during repairs and more power at the machines, for friction represents lost power.

To Increase H_2SO_4 Output.

Announcement has been made by the Tennessee Copper Co., New York that the output of its sulphuric acid plant at Ducktown, Tenn., will be increased to 3,000,000 tons annually.

Monsanto Works Acquires Acids Plant.

Following an increase in capitalization to \$5,000,000, the Monsanto Chemical Works, St. Louis, Mo., will carry on the manufacture of sulphuric, nitric and carbolic acids at its recently acquired plant at East St. Louis. The plant was purchased from the Commercial Acid Co.

Nitrates for Government Explosives.

The Atlas Power Co. has begun the construction of a \$6,000,000 plant for the manufacture of ammonium nitrate from sodium nitrate and ammonium sulphate. The plant will be located at Perry Point Farm, Md., and at the end of the war will be taken over by the U. S. government.

Enzymes

(Concluded from page 170)

Before baking the wheaten loaves (*Figs. 10 and 11*) the dough containing the mixed enzymes showed rapid raising power while at rest, with cracking of the outer pellicle. No sugar was added or required, due to the presence of saccharifying as well as fermenting and peptonizing enzymes.

The reason why enzymes withstand high temperatures in the dry state is due to lack of sufficient water to hydrolyze the "KEY," or anhydrid.

Acids, alkalies, H or OH ions and metallic salts, all destroy the protective colloid, hydrolyze the "KEY," or anhydrid, and kill the enzyme.

When enzymes are inactivated by elevated temperatures, the activity, or "KEY" is at times slowly regenerated on long standing. This is due to the re-combination, by the colloid, of the acid formed by the freed anhydrid.

Finally, it is the writer's belief that, having set forth the basic principles of those mysterious bodies known as enzymes and the method for their synthetic preparation, no longer is it necessary to say, with Prescott, that "only by their works shall they be known."

Cost of Creating a Merchant Marine.

(Concluded from page 178.)

ship construction—a total of 636, of 3,124,000 deadweight tonnage. Shipbuilding program contemplated under additional Congressional authorization—a total of 600, of 5,000,000 deadweight tonnage. "Some" program—"some" merchant marine for a starter!

So to the German U-boat havoc America torpedoes back appropriations almost to the $2,000,000,000 mark, warning the Hun that the new commercial supremacy of the seas shall not go to Germany and that 1,636 new ships with an aggregate tonage of 10,924,000 will meet and beat his futile U-boat menace. And America's confidence and reliance that this shall come to pass, is backed by the patriotism that has found a new and effective consecration in the pouring out of billions for Liberty Loan bonds.

Industry in War Times.

(Concluded from page 180.)

and hearings, to determine what are the less important industries, measured by the extent of their contribution, directly or indirectly, toward winning the war.

3rd. To promulgate such findings and to prepare, present and, if practicable, enforce such definite and concrete plan or plans as will result in—

- (a) Stimulating the operation of industries of exceptional importance.
- (b) Curtailing the operation of the less important industries or, **in the alternative, encouraging such industries so to change their operations as to produce war needs.**
- (c) Conserving the supply of essential raw materials as reserves to be drawn upon to meet the war requirements.

Artificial Dyestuffs in Italy.

(Concluded from page 177.)

growing dread in Germany of American competition. They are as follows:

"The manufacture of coloring matter has been gradually improved in all Allied and neutral countries, and there is no doubt that against the pre-war monopoly of Germany a powerful competition has arisen; that by breaking, at least in part, the monopoly will give to the commerce of these products a thoroughly different character. If the success of some of these competitors may be doubted, there is no question that Great Britain has already achieved a very noteworthy step forward towards independence. This may be said also of the United States of America, that has reached a very high stage of progress in the manufacture of these products, and promises not only to satisfy all home demands, but also to commence a large shipping trade.

"Those who have been able to read of late the German technical publications will have noted that, while they are hopeful of the possibility of meeting English competition, they regard with real anxiety the development of the American industry, so unexpected and so formidable.

"On the other hand, it is certain that the German industry is preparing itself for an enormous effort to reconquer the monopoly previously enjoyed; an effort that has only been made known abroad by the formation of a trust, having a capital of a milliard of marks, and comprising without distinction all the color works. The nature of the enormous technical efforts to be employed is, however, kept secret.

"A formidable battle will therefore take place between the German chemical industry and its competitors for the monopoly of the world's market: and this is foreseen to be so formidable that the Swiss firms preferred to retain their neutrality at present, desiring to see how matters shape, and continuing for the moment in their exceptionally favorable position from which they reap all possible advantage."

This feeling in Europe that our American color industry is firmly rooted and that it is bound to be a growing factor in world trade is practically an echo of the conviction in the hearts of those engaged in making it a success that the period of uncertainty is past. It requires only the continuance of the same unwearied pluck and versatile adaptation which have been displayed during the past two and a half years to ensure the final triumph.

FOREIGN TRADE OPPORTUNITIES

These Opportunities for Foreign Business Relations Are Made Public by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce, Washington, D. C. Names, Addresses and Details May Be Obtained from the Bureau or Any of Its Branches. Refer to the Number of Each Opportunity and Place Inquiries for More Than One on Separate Sheets.

Dyes.

26100—A firm in China desires to secure an agency for the sale of dyes. Cash will be paid, if necessary. The firm will also make outright purchases. Correspondence may be in English. References.

Pyrometers.

26218—An agency is desired by a man in France for the sale of agricultural motor pumps and dynamos for lighting. Also gas ovens and pyrometers. Correspondence should be in French. Reference.

Chemical Products and Oils.

20030—An agency on a commission basis is desired by a man in France for the sale of metals, industrial oils, chemical products, rubber, leather, and wood. Correspondence may be in English. References.

Industrial Chemicals.

26072—A man in France desires to represent American manufacturers and exporters of a general line of goods, such as food products, greases and oils, industrial chemicals, cereals, general light hardware, etc. All business is desired on a commission basis. Correspondence should be in French. References.

Calcium Carbide.

26061—A man in Alberia is in the market for 10 tons of calcium carbide. One-fourth cash will be paid with order and balance against presentation of documents at destination. The goods should be packed in casks weighing between 50 and 70 kilos. Correspondence should be in French. Reference. Prices should be quoted in francs, if possible.

Chemical Products.

26097—A man in Portugal is in the market for chemical products. Quotations should be made f. o. b. New York. Payment will be made against documents. Correspondence may be in English. References.

Dyestuffs and Chemicals.

26299—A firm in Argentina desires to receive agencies from American firms for the sale of dry goods, hosiery, tapestry, office supplies, chemicals, and dyestuffs. Correspondence may be in English. Reference.

Phosphoric Fertilizers.

25821.—A firm in the Azores wishes to buy phosphoric fertilizers, sulphuric copper, and sulphuric iron. Lowest cash quotations are desired f. o. b. New York. Correspondence may be in English.

Heavy Chemicals, Dyestuffs, Acids.

26343.—A business man in Australia wishes to purchase cocoa butter, cocoa beans, vegetable and carbon blacks, lithopone, essential oils, liquorice, bark extracts, heavy chemicals, dyestuffs, hematin, white and red lead, zinc oxides, formic acid, lactic acid, glues and gelatine, turpentine, peroxide soda, cornuba wax, vanilla crystals, and pigments. Payment will be made by letter of credit or in London. References.

Machine for Oil Extraction.

26367.—A merchant in Africa desires to purchase a small machine for the extraction of oil from sesamum seed. Payment will be made by cash against documents at destination. Correspondence should be in French or Italian. Reference.

Rubber and Leather Beltings.

26378.—A man in Canada who represents wholesale merchants and manufacturers in the Netherlands is in the market for rubber tires for bicycles, motorcycles, and automobiles; rubber, balata, cotton, and leather beltings; lubricating oils, greases, and graphite. Quotations should be made f. o. b. New York. Terms will be arranged through New York bankers against bill of lading.

Industrial Chemicals, Dyes, Paints.

26520.—A firm in the United States with branches all through the Far East desires to be placed in communication with American manufacturers and exporters of steel and iron products, hoop iron, box strapping, rails, wire and wire nails, industrial chemicals, disinfectants, dyes and drugs, paints, varnishes, building material, machinery, beer, wines and spirits, and canned goods. A representative of the firm is leaving for the Orient, and they desire to receive offers from American firms desiring to extend their trade to Java, Siam, French Indo-China, China, Japan, and the Celebes Islands. References.

DISTILLATES

News Notes of Chemical and Allied Industries

To Make Direct Cotton Colors.

The manufacture of direct cotton colors will be begun immediately at the new $50,000 plant of the American Color Co., at Scranton, Pa.

To Re-Build Plant.

Work will be begun at once by the Webster-Warnock Chemical Co. to reconstruct its chemical manufacturing plant at Memphis, Tenn., which was recently destroyed by fire with an estimated loss of $25,000.

Potash as Portland Cement By-Product.

Announcement has been made by the Ogden Portland Cement Co. that if experiments now being made prove satisfactory, the manufacture of potash will be undertaken at once at the company's plant at Baker, Utah.

Jefferson Graphite Co.

The Jefferson Graphite Co. has been incorporated with a capital of $20,000 at Birmingham, Ala., to engage in the production of graphite by George R. Sincix, L. B. Gunville and M. Hughes, Birmingham.

Norcross Co. to Make H_2SO_4 and HNO_3.

A sulphuric and nitric acid plant is being erected at Pueblo, Colo., by the Norcross Chemical Co., of Denver. The engineers in charge of the construction are from the Kalpberry Corp., New York.

Du Ponts to Load More Shells.

Plans are going forward for the construction of a new shell-loading plant by the E. I. du Pont de Nemours Co., Wilmington, Del. The plant will be located at Dundalk, Md.

Grasseli to Make Nitric Acid.

Construction work has already begun on a nitric acid plant costing $1,000,000 to be erected at New Castle, Pa., by the Grasseli Chemical Co. The plant will form an addition to the company's Covert's Station Powder Plant.

Fries & Fries to Operate Yonkers Plant.

Fries & Fries will manufacture water-proof coatings, syrups, etc., at Yonkers, N. Y., according to recently completed plans.

Richfield Oil Co. Increases Holdings.

The Richfield Oil Co. has recently acquired the plant of the Phoenix Refinery Co., Bakersfield, Cal., and has under consideration the construction of a local compressor plant for the extraction of gasoline from high gravity oil.

Maas & Waldstein to Enlarge Plant.

At Newark, N. J., the Maas & Waldstein Co., manufacturers of chemicals, are planning for the erection of a new addition to their plant in Avenue R to cost $12,000.

Independent Chemical Co.

With a capital of $4,500,000, the Independent Chemical Co. has been incorporated at Dover, Del., to manufacture chemicals and allied products. The incorporators are W. B. Walsh, Brooklyn, N. Y., J. A. Lyon, New York City and V. Harris, Pelham Manor, N. Y.

Krayer Chemical Co.

The Krayer Chemical Co. has been incorporated with a capital of $50,000 at Elizabeth, N. J., to manufacture chemicals, by Dr. Stephen S. Krayer, A. Krayer, H. Jacobs and Clarence S. Myer, Elizabeth.

Alphano Humus Co.

With a capital of $4,000,000, the Alphano Humus Co. has been incorporated at Boonton, N. J., to engage in the manufacture of fertilizers. The incorporators are John N. Hoff, Boonton, Richard Sellers, Bellevue, Del., and James E. Mantee, Portland. Me.

Johnson Chemical Co.

With a capital of $200,000, the Johnson Chemical Co. has been incorporated at Raleigh, N. C., to manufacture chemicals and kindred specialties. The incorporators are James I. Johnson, James I. Johnson, Jr., and J. W. Cross, Raleigh.

Liberty Leather Co.

The Liberty Leather Co. has been incorporated at Dover, Del., with a capital of $100,000 to manufacture leather and leather products by M. L. Horty, F. D. Buck and K. E. Longfield, Wilmington.

Day Chemical Co.

The Day Chemical Co., with a nominal capital of $5,000, has been incorporated at Chicago, Ill., to manufacture chemicals and allied products. The incorporators are Jas. D. Day, Robert A. Levener, R. H. Clinton and Hilgard B. Young.

McCarthy-Fox Chemical Co.

The McCarthy-Fox Chemical Co., Manhattan, has been incorporated under the laws of New York with a capital of $1,000, to deal in chemicals, drugs, etc. Incorporators are William V. McCarthy, M. C. McCarthy and Alfred J. Fox.

THE *SIXTH* OF MAY THRIFT STAMP DAY IN THE U. S. A.

Important Change of Date

Thrift Stamp Day Advanced to Monday, May 6th

It has been decided to advance Thrift Stamp Day in the U. S. A. from the First of May to the *Sixth* of May, in order to avoid conflicting with the wind-up of the Liberty Loan Drive which ends May 4th.

This Change of Date Will Help the Success of Thrift Stamp Day

It gives American business five days more to prepare for "The Biggest Business Day in History."

It means that the American people will have nothing else to distract their attention from Thrift Stamp Day.

May 6th is a Monday, which means that Thrift Stamp Day will fall on the day when people will have more money to invest in Thrift Stamps and to buy things at the Special Thrift Sales.

Capitalize on the situation which now prevails in the industrial chemical field.

Never before has the opportunity for business in chemical manufacturing and allied fields been as great as it is to-day.

The present demand for equipment, apparatus and chemical products runs into big figures.

The CHEMICAL ENGINEER is the connecting link between producer and consumer in this great field. Your advertisement in its pages would prove a *profitable investment*—not an expense.

THE CHEMICAL ENGINEER

U.S. Acid Proof Paint

SEND FOR SAMPLE ON TIN—READY TO TEST

This paint is proof against the most destructive acids and alkalis, or fumes of the same, in any strength, even to chlorine. It is also proof against steam conditions and dampness.

U. S. ACID PROOF PAINT contains no oil, asphalt, coal tar or pigment. It air dries in about 30 minutes and is permanently flexible. It will adhere to any surface, will not dry out, crumble or peel, and is non-deteriorating even when subjected to the most severe conditions. It is a deep black, will stand dry heat to 350 degrees Fahr. and is highly electrolysis proof.

One complete set, bound volumes, of the CHEMICAL ENGINEER, Vols. 1 to 25, inclusive. Also send for list of back numbers wanted. Address Editor, 118 E. 28th St., New York City

YOU ARE NOT ASKED TO GIVE—

INVEST!

The United States Government is anxious to pay you a good rate of interest on your spare change. Think of *that* the next time you spend a quarter on some unnecessary trifle. The belief that one quarter is too small to make any difference is highly gratifying to a certain Emperor. You must *keep on investing*—try buying just one Thrift Stamp *every day*—and watch your money grow.

HELP YOURSELF *HELP YOUR COUNTRY*

BUY WAR SAVINGS STAMPS

Bring Us Your Dyestuff Problems

The application of dyestuffs to textiles is as important as their production. The technique of this branch of the color industry has for years commanded the best talent among those dyestuff distributors who have catered to the highest class of trade.

An intimate knowledge of the possibilities of every dyestuff is often necessary to meet the particular requirements of the consumer. Dyeing is a chemical, not a mechanical, process, and the variation of local conditions, due to differences in quality of water, steam and chemicals, makes the dyehouse problem an individual one.

Such problems are welcomed by the technical department of this company, which is manned by chemists who have been picked because of their knowledge, practical experience and demonstrated ability. We have long maintained well-equipped laboratories at our different offices for this purpose, and invite inquiries and extend, without any obligation on the part of our customers, our services to all who stand in need of them.

CHARLES B. DAVIS, F. C. S., Consulting Editor

Entered as Second Class Matter at the Post Office at New York, N. Y., under the Act of March 3d, 1879.

Subscription—United States, Cuba and Mexico, $2.00; Canada, $2.50; other countries, $3.00. Single Copies, 25c.

Statement of the Ownership, Management, etc., Required by the Act of Congress of August 24, 1912,

Of the Chemical Engineer, published monthly at New York, N. Y., for April 1st, 1918.

County of New York, State of New York, ss.

Before me, a Notary Public in and for the State and county aforesaid, personally appeared Robert H. McCready, who, having been duly sworn according to law, deposes and says that he is the Business Manager of the Chemical Engineer, and that the following is, to the best of his knowledge and belief, a true statement of the ownership, management (and if a daily paper, the circulation), etc., of the aforesaid publication for the date shown in the above caption, required by the Act of August 24, 1912, embodied in Section 413, Postal Laws and Regulations, printed on the reverse of this form, to wit:

1. That the names and addresses of the publisher, editor, managing editor, and business managers are: Publisher, McCready Publishing Co., 118 East 28th St., N. Y.; editors, Thos. H. Norton, 118 East 28th St., N. Y.; L. T. Clark, 118 East 28th St., N. Y.; managing editor, none; business manager, R. H. McCready, 118 East 28th St., N. Y.

2. That the owners are: C. J. O'Brien, 22 North William St., N. Y.

3. That the known bondholders, mortgagees, and other security holders owning or holding 1 per cent. or more of total amount of bonds, mortgages, or other securities are: None.

4. That the two paragraphs next above, giving the names of the owners, stockholders, and security holders, if any, contain not only the list of stockholders and security holders as they appear upon the books of the company, but also, in cases where the stockholder or security holder appears upon the books of the company as trustee or in any other fiduciary relation, the name of the person or corporation for whom such trustee is acting is given; also that the said two paragraphs contain statements embracing affiant's full knowledge and belief as to the circumstances and conditions under which stockholders and security holders who do not appear upon the books of the company as trustees hold stock and securities in a capacity other than that of a bona fide owner; and this affiant has no reason to believe that any other person, association, or corporation has any interest direct or indirect in the said stock, bonds, or other securities than as so stated by him. ROBERT H. McCREADY.

Sworn to and subscribed before me this 1st day of April, 1918.
FREDERICK PFISTER.

The Logwood Supply of Haiti

Haiti has been for many years among the sources of supply for logwood. The United States has imported annually from 50,000 to 100,000 short tins for over twenty years.

The logwood has, thus far, been derived chiefly from the forests adjacent to the coast. The interior contains large tracts of logwood growth practically untouched and awaiting modern methods of transportation. At present, the annual cut is far from representing the equivalent of the annual growth of logwood. During the unprecedented high prices for logwood prevailing during 1915-16 considerable amounts were cut in the interior and brought to coast ports, but were not shipped until the sudden break in quotations made it impossible to sell without loss. Vast stocks of these accumulations, at various coastal points, still await purchasers. The world's demand for logwood will be permanently much in advance of the consumption of 1913-14. There would seem to be an admirable opportunity to lay the foundations for a permanent exploitation of the Haitian inland forests, by constructing a few short lines of railway and establishing the facilities for easy and expeditious shipment. Conditions are favorable for American capital to secure an economic position on the island, which may be of the greatest value ultimately.

THE AMYLO SACCHARIFICATION PROCESS

By

J. S. HORN

As a result of a paper read before the Society of American Bacteriologists at its 19th annual meeting, December 27, 1917, in Washington, D. C., on "The Importance of Pure Culture Work in Industrial Processes," several interesting communications have been received which indicate that the "Amylo Process" is very little understood indeed.

The information has been received from one source that, some years ago, a Peoria concern had a mold process installed which apparently proved a failure. Not knowing the details of this process, it is quite difficult to point out the reason for this. It may be said, however, that the director must combine the following qualifications in order to successfully work out a process of this type on an industrial scale, i.e.: (1) He must be an excellent manipulator in pure culture work; (2) he must be a good chemist and able to put theories into practice; (3) he should have a fair idea of constructive engineering; for unless the plant is well laid out, the consumption of steam and the chances of infection, etc., are materially increased.

A second argument advanced is that the amylo process cannot compete with the malt saccharification process. This has been disproved repeatedly. One concern was persuaded to employ the malt process after running the amylo for two years. A one month's run convinced them thoroughly as to which was the cheaper. The writer has built one plant and operated it for two years, and operated another for four and a half years. The following is the economic side as outlined for a southern concern:

A company in the South operated an 1800 bu. house during 1917. The yield per bu. never exceeded 4.80 proof gallons. A check on a one day's run revealed that 160 bu. of corn in excess of the amount allowed were used to obtain a fair yield. The manager, well versed with Middle West distilleries and reputed to have obtained yields as high as 5.13 P. G. per bu. of corn, left after a one week's run. The reason was obvious. The plant is poorly installed and the climatic conditions are such that the malt process and the highly treasured jug yeast (which grandma brought from Ireland three generations ago!) were a total failure. However, these same conditions are all in favor of the amylo process.

Mr. J. C. Mims, Industrial Chemist of New Orleans, was commissioned to investigate the practicability of the amylo process of saccharification. His recommendation favored proceeding with the installation. The preliminary work revealed the following facts:

Total mashing capacity of the small unit	1800 bu.
Small grain (rye and malt) 56 lb. per bu.	11% $2.75 per bu.
Corn per bushel	89% $1.61 per bu.
Cost price of 1800 bu	$3,123.72
Value of residue (dried distiller's grain) at $40.00	270.00
Total	$2,853.72
Total production of alcohol (4.80 P. G per bu.)	8640.00 P. G.
Cost price of grain only, per proof gall	$0.31

Saving due to superiority of amylo process:

Corn at $1.61 per bu. 1800 bu	$2,898.00
Total alcohol produced (5.20 P. G. per bu.)	9,360.00
Difference in cost price of grain	$ 225.70
Increased value of production	259.90
Increased value of distiller's grain	180.00
	$665.60
Total in favor of amylo process per year of 312 days	$207,667

The cost of installing the additional equipment was about $35,000, or, let us say, $45,000, to meet any unforeseen war prices in material. Thus it may be seen that an investment of $45,000 would not only conserve 43,200 bu. of corn per year—which is of vital importance to Mr. Hoover's work just now—but in addition would bring $207,667.20 at the most conservative estimate at prevailing prices, or approximately 461.5% on the capital invested. In normal times the margin of profit would be smaller of course, but still worth while.

This does not take into consideration the economies due to saving in steam, water, labor, etc. The concentration of the amylo mash is 28 gals. per bu. of corn, instead of 45 gals. by the old process and $\frac{1800}{28} \times 45$ or about 2,900 bu. can be mashed in the 1,800 bu. equipment. Under these conditions 2,900 bu. of corn are worked much more economically than the 1,800 under the malt process. There was a $12,000 refrigerating machine, which was not needed because the mash was cooled to 40° C. only. The waste of cooling water and steam in the vacuum pump is something enormous in the warmer latitudes. The mash pump, running practically 12 hrs. to cool the mash of 1,800 bu., is also done away with. The mash is blown from the cooker into the amylo tank directly by its own steam pressure. After the tank is filled the mash may be cooled at leisure. Any one who has fought with poor water conditions in warm countries know what that means. A 3,000 bu. house of the amylo type can get along with a 5-inch water pipe line, while on the other hand this 1,800 bu. house had two 6-in. lines and most of the time either had to suspend cooling or shut down the vacuum pump.

The main operation—mashing—is carried on according to the following schedule: Obeying governmental restrictions in regard to operating a distillery, the amylo process must be carried out in two different operations, (1) mashing, saccharification, (2) fermentation. That is to say, the mash must be cooked into one tank, where saccharification is accomplished, and when the appropriate hour arrives, whether ready or not, this mash must be passed to another tank known as the fermenter. For this cooking the Government storekeeper weighs out 200 bu. of corn meal into each cooker, or 11,200 lbs., 3 cookers in a series, preferably of the Henze type—but any other will do.

The meal is slowly added to about twice its weight of water. The water is heated to about 60° C. to prevent caking of the meal and either steam or air is passed through the cooker to prevent the formation of lumps at the bottom of the cooker which would clog up to the mash outlet. At the same time the steam or air will assist in thoroughly mixing the corn meal and water. Enough acid is added to the water in the cookers to bring the final acidity of the mash to .3 g. HCl per liter. The purpose of the acid is threefold: (1) The alkalinity must be neutralized, for the mold requires a slightly acid medium; (2) the acidity in the cooker assits the disintegration of the cellulose, making the mash more susceptible to the action of the mold; (3) the basic phosphate salts of the grain must be transferred into acid salts.

The steam is turned on and the mash brought to a boil for 10 minutes. As soon as the air is expelled the steam outlet pipe on top of the cooker is closed and partly opened again to allow a slight continuous flow of steam. The exhaust from the cookers passes through a sterilizer to preheat the water for completely filling the amylo tank.

The steaming of the mash is done rather gradually. During the first half hour the pressure is brought to 10 lbs. The next half hour a pressure of 25 lbs. is reached and held for 10 minutes. This is raised to 40 lbs. in another half hour, and again held for 10 minutes. The pressure is allowed to go to 50-55 during the next 20 minutes. Hold 10 minutes and blow mash into the amylo tank by its own pressure, flush the cooker, if of the horizontal type, and allow excess pressure to escape through the sterilizer or the tank, as the case may be. It takes about 25 minutes to empty the cooker.

After all mash (600 bu.) has been transferred to the amylo tank the sterilized water is run in to fill the tank. The filling line is then disconnected and the pipe blind-flanged to do away with a possible source of infection. Air is now passed through a cotton filter and enters the bottom of the tank, which is provided with a stirrer. The filtered air bubbles through the mash, which is at 104° C., and escapes through a 4-in. pipe at the top of the tank. This outlet pipe passes through a barboteur where a 4-ft. water seal prevents any access of bacteria from that direction. The air removes all steam in the mash. In about 30 minutes turn on the cooling water very gradually at first to avoid vacuum within the mash tank. This may also be avoided by allowing more air to enter.

The cooling is accomplished by running a thin sheet of water over the outside of the tank from a pipe encircling the tank on top. The spray holes are about 3 inches apart and slant toward the sides. This method of cooling is slow, however, and very wasteful with regard to water consumption. About 10 to 12 hours are required to cool the tank from 104° C. to 40° C. It is advisable to install cooling coils, especially in the larger tanks (20,000 to 40,000 gals. capacity) in order to save time and cooling water. One hundred feet of a 2-in. copper pipe has proven very satisfactory—the cooling being accomplished in less than 6 hours, and the consumption of water less than in the first instance.

As soon as the temperature drops to 43° C. the mold is introduced. For this purpose there is a cock riveted to the top of the tank, which is provided with a rubber extension closed by a copper plug. An assistant with an alcohol torch carefully heats the plug, and also the neck of the 1 liter spore flask. The plug is now withdrawn and at the same time the neck of flask inserted and the mold spores poured into the tank. The stirring device, together with the air, thoroughly distributes the spores. When the spores are introduced germinating, in order to gain time, the wort is added to the flask about 6 hours previously. The time gained in saccharification is about 4 hours, but, on the other hand, there are some disadvantages. The mash may be too warm yet, or not very favorable in other respects, and the growth of the filaments greatly stunted when transferred from a favorable medium to a less favorable one.

Twenty-four hours after the addition of the spores a sample is taken from the tank in order to determine the purity (microscopically) and the amount of gemmae and filaments, which latter is seen best when suspending some of the mash in a glass of water. The growing mold is in appearance like so much cotton wool, and if any infection is present the mold shows a peculiar growth, not easily described, but immediately apparent to the practiced eye. The reducing sugars and the acidity are very important. The acidity is best determined by a standardized calcium hydroxid solution.

The specific gravity is not of importance except as an incidental check. While the gravity of the hot mash is between 14° and 15° Brix, as soon as the temperature drops some of the starch separates out and the gravity is about 11° Brix. This precipitated starch is easily attacked when saccharification is at its maximum. If the yeast culture is an old stock it may be added as soon as an increase of sugar is noted. However, if the yeast culture is fermenting it is not added until about 45 grams of sugar are present. In 24 hours the yeast is very numerous and fermentation proceeds rapidly. At this time the total sugar present should be between 95 gr. and 105 gr. per liter. If below, the yeast may gain too rapidly and the mold suffer, or, if above 105-110 gr., the mold may become sluggish so far as the diastatic action is concerned and settle down to feast on its products. In either case incomplete saccharification results.

Within the next 24 hours fermentation is at its height, and the gravity drops to about 1.0° Brix. In another 24 hours the gravity registered is about minus 0.3° to 0.5° Brix and the mash is ready for the still. The acidity may rise to 0.8 g. of H_2SO_4 per liter at the finish.

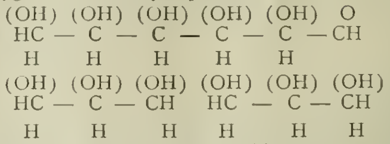
The residue may then be dried and the oil extracted, if the corn oil has not been removed before cooking. The filtering of the residue proceeds smoothly. The mold acts somewhat as a filter pulp or diluent of the extractive matter. The cake contains about 60 per cent. of water. An average analysis of the dried residue when the corn oil is not removed is as follows:

Moisture	6.0— 7.5%
Fat	19.0—23.0%
Protein	37.5—39.0%
Carbohydrates	38.0—40.0%
Ash	1.9— 2.5%

Synthetic Glycerine.

One of the most promising fields of the mucor application, however, may be the production of synthetic glycerine. While experimenting with bacteria of the *granulo bacter* variety, the writer found that whenever a hydrogen producing bacteria was working in an amylo mash, in the presence of calcium carbonate, the proportion of glycerine increased some 5 times over the normal The conclusion drawn was that nascent hydrogen is in some way connected with the phenomenon. A repetition of this, eliminating all other possible factors, proved the assumption to be correct, although it was noted that an alkaline condition existed at the same time. Previous to this it was observed in molasses fermentation, as well as amylo work, that alkalinity is essential to obtain a higher glycerine yield. The general conclusion is that the glycerine content is inversely proportional to the acidity of the mash and that the higher types of yeast produce less than the wild yeasts. The natural yeasts, like grape yeasts, in presence of cream of tartar, produce more than any pure culture yeast, but as soon as the acidity rises, due to fermentation, the glycerine content remains stationary. Whether this results from the increase in acidity alone, or perhaps from the decomposition of a certain amount of the glycerine formed, is difficult to determine without thorough research.*

Viewing the subject from a strictly theoretical point of view, we see that sugar has 5 hydroxyl groups and 1 oxygen in the aldehyde position:



$$\underset{H}{\overset{(OH)}{HC}} - \underset{H}{\overset{(OH)}{C}} - \underset{H}{\overset{(OH)}{C}} - \underset{H}{\overset{(OH)}{C}} - \underset{H}{\overset{(OH)}{C}} - \overset{O}{CH}$$

$$\underset{H}{\overset{(OH)}{HC}} - \underset{H}{\overset{(OH)}{C}} - \underset{H}{\overset{(OH)}{CH}} \quad \underset{H}{\overset{(OH)}{HC}} - \underset{H}{\overset{(OH)}{C}} - \underset{H}{\overset{(OH)}{CH}}$$

Fructose did not respond to this treatment and no glycerine was formed.

Thus in the presence of nascent hydrogen the position of the aldehyde oxygen becomes unstable and as soon as it assumes the hydroxyl state the molecule ceases to exist as sugar. The only possible substance it can be transformed into under the existing conditions is glycerine.[1] There is no difficulty in explaining the action. Oxidizing any aldehyde to the corresponding acid involves the introduction of an oxygen atom to form a hydroxyl in a hydrogen position. In this case the hydrogen acting on the oxygen liberates an additional valence which will be immediately satisfied by an atom of nascent hydrogen. This being accomplished, the substance becoming unstable will very naturally split symmetrically. The resulting two carbon valences will be satisfied by additional nascent hydrogen. The glycerine thus formed is saturated and consequently is *hors de combat.*

From this the deduction was made that if the sugar was hydrogenated to supply the 4 hydrogen atoms essential to the reaction, glycerine should result. Such was indeed the case. A glucose solution suspended in an oil, with finely divided nickel as a catalyst, (no palladium being available), was put under a steam pressure of over 100 lbs. and nascent hydrogen introduced. The yield of glycerine varied between 5 per cent. and 10 per cent. The factors were not worked out in detail but we may feel assured that glycerine can be manufactured from glucose.

The above experiments were conducted with the material resulting from the amylo process. It is probable that the reaction is far more complete when cane sugar is inverted, thus dealing with practically chemically pure substances.

Summarizing, we may say that the attempt to bring about the formation of glycerine by fermentation, on a profitable scale, has not yet succeeded. Whether alkaline fermentation will solve it remains to be seen.

Mucor and the Fermentation of Acetone and Higher Alcohols.

The application of the amylo process to bacterial fermentation is in its infancy. It is not known to the writer whether the mold saccharification has been applied to the manufacture of acetone, butyl alcohol, fusel oil, butyric acid, etc. While experimenting with so-called heat-proof bacteria in order to obtain fusel oil, it was noted that whenever the culture tubes were sealed off, a rather pleasant odor was observed upon opening the tubes. Subsequent tests in a rarified carbon dioxid atmosphere revealed that no butyric acid or fusel oil were present, but instead a large amount of an organic substance having a boiling point of between 60° C. and 110° C. Fractionation gave two distillates—one boiling close to 65° C. and the other close to 115° C. Repeated distillation brought the boiling point of the latter fraction to between 115° and 117° C. The first fraction was discarded at the time as impurities of the butyl alcohol. Further tests made at the Bacteriological Laboratory of the Louisiana Sugar Experiment Station with the generous permission of Prof. Taggart and Dr. Kopeloff, director and bacteriologist respectively, showed that the first fraction was the more valuable, namely acetone.

---

*Tests made with yeast obtained from Calif. Wine Assn., San Martin, Calif.; type unknown, season 1915.

[1] Sorbitol probably differs in constitution from hydrogenated glucose.

The bacteria servicable in this work belongs to family VIII, Bacillaceae, group 2, Clostridium Prazmowski 1880, according to the classification in the Journal of Bacteriology, Vol. 2, No. 5, page 562. These bacteria are very well described by Bredemann in *Zentralblatt fur Bakteriologie,* 2te Abt. Band 23, No. 1420, pages 386 to 568. While Bredemann made an attempt to prove that all different varieties are alike, it is well understood that some differ radically from the rest, especially in respect to the end-products of fermentation. The granulobacter pectinovorum, apparently the bacteria employed by Effront (U. S. patent 953,025; 3, 29, 10), and Bac. amylobacter are best adapted to this fermentation. The adaptation will take at least 6 months of careful cultivation. The butylic bacillus of Fitz, (Fernbach U. S. patent 1,044,368; 11, 12, 12) was not satisfactory at all and it is supposed that the diclosure is a camouflage. This patent refers to "a ferment of the character of the butylic bacillus of Fitz." The patent is so worded that any one filing a subsequent application cannot obtain a patent.

The method worked out takes advantage of the saccharifying power of the amylomyces alpha, beta or gamma, but the beta strain is perhaps better because it does not ferment any sugar. The bacterial culture may be introduced with the mold, but it is advisable to at least partially saccharify the mash. This will allow the mold to act on the nitrogenous bodies, making them available for bacterial metabolism. In a mash for this fermentation, which is preferably set around 10 degrees Brix, the mucor grows rapidly and in 10 hours the saccharification is well under way. As soon as the rise in sugar is noted the pure culture of the granulobacter is added.

These spore-forming bacteria are anaerobic. The air, which is essential for the development of the mucor, must be cut off as soon as the iodine test becomes negative and all air displaced by carbon dioxid. A partial vacuum will assist this process, but is not at all essential for the fermentation. In presence of air the same bacteria will form butyric acid to a large extent.

Normally, the bacterial fermentation is complete in from 48 to 55 hrs. The total time consumed is about as follows:

Cooking and filling of the amylo tank	5 hrs.
Cooling of mash to 40 C.	6 "
Development of the mucor	10 "
Saccharification	24 "
Fermentation (not over)	55 "
Emptying of tank	2 "
	102 "

It will be seen that about 4½ days are required for a complete cycle. The vinasse from this fermentation is, of course, utilized for butyric acid fermentation, in view of the fact that a complete change cannot be brought about. This is very important, for the reason that the process might prove a commercial failure, but for the saving of the by-products. A judicious addition of albuminoid matter may raise the yield about 5 per cent. A production of 20 per cent. of the weight of the grain may be counted on. Some precautions must be followed rigorously, as the bacteria changes very much until the habits are well established. Even then steady sporulation and sterilization must be practiced in order to keep the strain from degenerating.

The Production of Table Syrup.

Some experiments have been made to see whether it would be feasible to treat corn for the production of glucose by means of molds. The procedure is somewhat different. The cooking period must be shortened and the acidity kept as low as possible in order to avoid the formation of caramel. The production may be too low, though, when the corn is not sufficiently cooked, for the growth of the mold is very fast in this case. The diastatic power is not in proportion to the development of the mycelia.[2] If cooked too much, the caramel formed has an inhibiting effect on the growth of the mold and while the inversion is very complete the period is considerably lengthened. As before noted, the sugar content should at no time be more than 110 grams per liter for the reason that the mold would act on its own products. Therefore, the mash must be of such a concentration that when the total starch is inverted it does not contain more than 11 per cent. of sugar. About 45 gallons of mash to the bushel of corn mashed will give a solution of between 9.7° and 10.2° Brix, which when saccharified will give just the right amount of glucose. This saccharification is completed in about 36 hours. The glucose solution is now heated to 65° C. to complete the saccharification, which while killing the mucor seems to make the enzyme of the mucor readily available for additional inversion. Mashes up to 14° Brix have been satisfactorily inverted in that manner, when 11° Brix would have been about the maximum.

The liquid is then filtered, the residue containing the mold is pressed and the solution added to the filtrate from the filter press. The protein matter may now be precipitated as well as the dextrine, and the filtered solution concentrated, passed over vegetable bleaching char, (that made from southern yellow pine has been

COMPARATIVE TESTS OF PORCELAIN LABORATORY WARE

By

C. E. WATERS*

Porcelain is of but slightly less importance than glass in the chemical laboratory. In ordinary use it soon becomes evident whether or not the ware is mechanically strong and whether it is able to withstand sudden changes in temperature. In exact analytical work it is equally important that the glaze should offer the maximum resistance to attack by reagents. For many years chemists had at their disposal certain makes of ware which were of excellent quality, so that the resistance of porcelain to reagents was almost a laboratory byword. The placing on the market of ware from other sources and the inability to obtain the familiar brands made it desirable to subject both the new and old kinds to a series of comparative tests.

At the outset it was recognized that the results would probably not be as clear cut and definite as those with glass. The weight of the porcelain prevented the testing of crucibles and dishes above a certain limited size. This meant that only a small surface of presumably highly resistant material would be exposed to attack. In addition, the shapes of the crucibles, and still more of the dishes, varied for the different makes, so that with a given volume of reagent not necessarily the same area of glaze would be attacked. During the progress of the work it was found that this factor was of slight importance, because the losses due to the action of the reagent were usually so small as to be negligible for most analytical work. After all it is desirable to know to what extent a given volume of solution may become contaminated, rather than how many square centimeters of porcelain it will wet.

Brands Tested

At the time the tests were made only five makes of glazed porcelain ware could be obtained. In the laboratory stock the necessary number of Royal Berlin dishes, but no crucibles, was found. Meissen ware could not be obtained, but dishes and crucibles of "Bavarian" ware were purchased. In addition to these, a supply of Japanese brand, marked "S. C. P.," and of two American makes, Herold (Coors) and Guernsey, were bought. All of the purchases were made in the open market.

The dishes were the largest that could be placed upon the balance pans. Nominally 80 mm in diameter, they varied from 78 to 95 mm for the different makes. The crucibles ranged in height from 35 to 50 mm, and in diameter from 57 to 65 mm. The different pieces of any one kind of ware were quite uniform in diameter and in general shape, but the variations in thickness were rather large. This was shown by the weights, which varied as follows: Herold (Coors), 34.5 to 43.1 g; Guernsey, 36.2 to 44.5 g; Bavarian, 34.1 to 43.0 g; Berlin, 29.4 to 37.3 g; Japanese, 32.3 to 43.0 g. The last-named ware showed the maximum variation, which amounted to 33 per cent. These figures are for 33 to 36 dishes of each kind of porcelain.

Preparation of Pieces

Each piece was roughly weighed and, after having been arranged in the order of its weight, was lightly marked near the rim by means of a writing diamond. During the tests no breaks started at these diamond scratches. The lightest piece of each kind was used as a tare against which all weighings of that ware were made.

The pieces for the heating tests were not cleaned further than by wiping with a damp towel before the first rough weighing. The pieces used to test the action of reagents were rinsed with water, hydochloric acid (1:1), and again with water, after which they were wiped dry on the outside. They were then kept filled with distilled water for 20 hours, rinsed, wiped dry, heated to 110° for two hours, cooled in the air, and weighed not sooner than three-fourths hours and usually much longer after their removal from the air bath. The tares were heated with the test pieces before each set of weighings.

Selection of Test Methods

Suggestions as to the methods of testing and the reagents to use were received from various sources. No particular search of the literature was made, but it is believed that the fusions with sodium nitrate and the ignition with ferric oxide are new. The reasons for most of the tests are obvous, and for the others are given further on.

Experimental

All tests were made in duplicate, and the results are given in tabular form.

Sudden Cooling

Each piece was three-fifths filled with paraffin at 100° C, then brought to the desired temperature on a hot plate. It was then floated on water at room temperature. There were no failures on cooling from 200° C, but a number of dishes and crucibles cracked or broke when they were cooled from 225° C.

---

*Chemist, U. S. Bureau of Standards. From a recent Technologic Paper issued by the Bureau.

Sudden Heating

The pieces were placed on a wire triangle and heated in the full flame of a Fletcher burner of the Méker type. After 3 minutes the flame was removed and 10 seconds later the piece was removed with platinum-tipped tongs. By this time the porcelain had cooled to a pale straw-yellow, at which temperature it would ordinarily be placed in a desiccator or otherwise handled with tongs. Quite unexpectedly this proved to be an important test, for in many cases the glaze cracked where touched by the tongs. When this happened after the first heating, new cracks were formed after one or more of the three succeeding heatings of 2 minutes each. In no case did the cracks first appear after one of these later heats.

The Royal Berlin and Japanese wares withstood this test satisfactorily.[†]

Treatment with Sodium Hydroxide.

After the usual preliminary cleansing, drying, and weighing, each piece was placed on the steam bath and then 50 cc of 10 per cent. sodium-hydroxide solution was carefully poured in. The dishes did not rest in the openings of the bath but on thin plates of aluminum, in order to avoid the solvent action of directly impinging steam. After five hours' heating, 30 cc of water was added to each dish to make up for that lost by evaporation. An hour later the pieces were rinsed out under the tap, dipped into hydrochloric acid (1:1), again washed, wiped dry, heated in the air bath, and finally weighed after cooling in the air. A second treatment exactly like the first was given.

The losses in weight were greater than those caused by any other reagent, but the crucibles gave so much lower figures than the dishes that only the latter were used in the remaining solubility tests.

Treatment with Sodium Carbonate

The solution used contained 100 g of the anhydrous salt in 1,000 cc. The dishes were cleansed as for the preceding tests. There were two treatments of seven hours each. The losses by evaporation were made up by adding 10-cc portions of distilled water at intervals of about two hours.

Treatment with Sulphuric Acid

The cleansed and weighed dishes, each containing 25 cc of concentrated sulphuric acid, were heated on a hot plate for three hours at a temperature high enough to cause strong fuming. After washing out the acid and drying and weighing the dishes, it was noticed that one of them had a small crevice in the edge. Since this still contained acid, all the dishes were soaked in distilled water for three hours, rinsed, dried, and again weighed.

Treatment with Fused Sodium Nitrate

Since no oven suitable for use at temperatures above the melting point of sodium nitrate was available, the dishes were heated over burners. Thirty grams of the salt were placed in each dish and kept for two hours at such temperature that there was a slight crust around the edges, while most of the nitrate was in the fused state. The melted salt was poured out and the cooled dishes were soaked for one and one-half hours in running water, then rinsed with dilute hydrochloric acid followed by distilled water. They were wiped dry, heated to 110° C, cooled, and weighed.

The losses in weight under this treatment were so unexpectedly small that a new series of tests were made with the same dishes at a higher temperature. The same weight of nitrate as before was slowly heated up to the point at which a piece of charcoal floating on it caught fire. This required about 10 minutes. Under this treatment there were further losses, but the figures in the table, which show the combined losses during the two fusions, were still small.

Treatment with Fused Sodium-Nitrate-Carbonate Mixture

A mixture of 10 parts of sodium nitrate and 1 part of carbonate readily fuses to a clear melt at a temperature higher than the melting point of the nitrate alone, yet still below a red heat. The action of even this strongly alkaline reagent was slight when 33 g of it was kept just at the melting point for two hours. After the usual cleansing and weighing the dishes were soaked in distilled water overnight. The very small changes in weight thus resulting are evidence against any considerable porosity of the porcelain. The figures in the table give the total losses during the three fusions.

The glaze at the bottom of some of the dishes was dulled, but did not appear to have been badly attacked.

Ignition with Ferric Oxide

Ferric oxide so readily stains porcelain and is often so hard to remove as to suggest that it forms a silicate with the glaze. In this case the removal of the stain by prolonged digestion with hydrochloric acid might be expected to remove silica in soluble form, and possibly also other constituents of the altered glaze.

In order to coat the dishes as uniformly as possible with ferric oxide before ignition, the following procedure was adopted: To 20 cc of a solution of ferric nitrate (equivalent to 57 mg of Fe_2O_3) was added 5 cc of ammonia of half strength. The whole was evaporated to dryness, first on the steam bath and then in a radiator[‡]. This was followed by gentle ignition over a small flame and finally five minutes' heating in the full flame of a Fletcher burner. After cooling, the dishes were wiped as clean as possible and weighed. Although all were badly stained, their increase in weight due to adhering ferric oxide was in no case as much as 1 mg. To each dish there was added 40 cc of hydrochloric acid (1:1) which removed the stains by digesting on the steam bath for three-fourths hour. The dishes were soaked in running water for one hour, then cleaned, dried, and weighed. The losses in weight were all very small and gave no evidence of the formation of any considerable amount of soluble silicates.

[†] Samples of Coors ware of recent manufacture have been found to withstand this test.

[‡] Hillebrand, Bull. 422, U. S. Geol. Survey, p. 31, 1916.

Porosity

The dishes that had been used in the nitrate fusions were soaked overnight in an aqueous solution of methyl violet, then rinsed quickly and wiped dry. All were strongly colored around the unglazed rim, and the numbers scratched on by the writing diamond stood out plainly. The spots where the glaze was dulled were faintly dyed. Nearly all of the color was removed by soaking for 20 hours in distilled water. In no case was there any evidences of pores or channels in the body of the material. The purple band around the edge was sharply limited by the glaze and showed no sign of creeping in under it. The dyeing effect seems to be due to adsorption by the rougher parts of the surface.

Decrease in Sicilian Sulphur Exportations

Consul Robertson Honey, Catania, Italy, writes that during the first ten months of the calendar year 1917, Catania exported 40,496 metric tons of refined sulphur as against 80,672 tons for the corresponding period of 1916. Continental Italy, France and England were the heaviest buyers (in the order named) and together took over 72 per cent. of the output of the entire island of Sicily. Of crude and refined sulphur combined Catania exported 51,120 tons in the 1917 period, as against 89,810 tons in 1916. The entire island during the two periods exported 143,002 tons in 1917 as against 383,329 tons in 1916.—Commerce Reports.

Nevada Cyanide Plant Running.

Production has been begun at the new 150 ton electrically operated cyanide plant of the Elkoro Mines Co. at Jarbridge, Nevada.

Represented A. C. S. at Chicago.

Dr. Julius Steiglitz, A. V., Mory and William Hoskins represented the American Chemical Society as delegates to the recent Congress of National Service held in Chicago.

Commercial Cylinder Co.

To manufacture gas, oils, etc., The Commercial Cylinder Company, Hackensack, N. J., has been incorporated under the laws of that State with a capital of $800,000. The incorporators are A. R. Oakley, Pearl River, N. Y., and Paul E. Britsch, Brooklyn.

Lambert Chemical Co.

The Lambert Chemical Company, St. Louis, Mo., has been incorporated with a capital of $30,000 to manufacture chemicals and allied products. W. and A. W. Lambert and A. R. Deacon, St. Louis, are the incorporators.

Will Make Fertilizer and Phosphate.

The Merchants Fertilizer and Phosphate Company, Charleston, S. C., has been incorporated with a capital of $25,000 to manufacture fertilizer and phosphate. The incorporators are E. H. Pringle, Jr., B. G. Pringle, F. E. Barron and A. F. Pringle, Charleston.

Germans View Dye Future "With Confidence."

According to the *Journal of the Society of Dyers and Colorists*, the annual report of the German color combine contains the following statement:

"Owing to the length of the war numerous competitive works have been established in neutral and enemy countries. A hard struggle with them is bound to come after the war. Sacrifices will undoubtedly have to be made; nevertheless, the future position may be regarded with confidence."

German Dye Recipes for British Textiles

Consul Augustus E. Ingram, Bradford, England, writes in Commerce Reports that since the publication in a newspaper in this country on January 10 of the account of the success of a group of men in the British textile trade in bringing to England from Switzerland 257 secret recipes for the manufacture of aniline dyes, which have been in use in the Bidische chemical factories in Germany, the Yorkshire newspapers have had many articles on the subject, the majority of which state that considerable skepticism is felt on the subject by dyeing experts. The following views have been gathered from published statements and discussions:

Do Not Represent Whole Industry.

The British Board of Trade is reported to have said that as yet it had had no opportunity to test the merits of the claim. It was pointed out that the Badische Co. is only one of several German companies engaged in the manufacture of dyes. One of the latest catalogues gives exactly 1,001 dyes, each representing a distinct color, while the modifications—the finer shades of similar colors—run at least to 2,000 or 3,000. Different firms offer similar things under varying names, so that 257 recipes—a term which is not in accordance with the technology of the trade—must not be taken to represent the whole of the German dye industry.

One paper says that while recipes are of value, much more is necessary to put the domestic dyeware industry in a position after the war to meet the keen competition that is bound to be experienced from the formidable combinations that exist in Germany. There is need of large expenditure of capital, coordination, and efficiency of working.

Present Limitations in Production.

The absence of German aniline dyewares has compelled dyeing firms in England to turn to the natural dyewares, which, as is well known, involve more labor than artificial colors, while, of course, natural dyes can not be standardized or guaranteed as in the case of aniline dyes. The result has been that dyers for some time have had to limit the number of their shades and to withdraw their guaranties as to fastness. In other words, dyers have been content, more or less, to accept what they were able to get, thus creating an easy market for makers of dyewares.

The complaint of those who take a long view of this problem is that instead of utilizing the opportunity afforded by having the market to themselves to make such progress as will enable them to compete successfully with the Germans after the war, dyeware manufacturers in England have devoted far too much attention to the making of immediate profits. Mention is also made of petty rivalry between dyeware makers in the country.

On the other hand, practical men in the trade say that several firms are now producing important dyes that were not made in England before the war. Not long ago British Dyes (Ltd.) announced the production of the first three of a series of vat colors, the latest dyes put on the market by the Germans before the war, and other firms have been similarly energetic and enterprising in research work.

Too Much Emphasis on Secret Processes.

Prof. Arthur G. Perkin, head of the dyeing department in the University of Leeds, is reported in the Yorkshire Post to have said that he reserved judgment until a statement on the subject was forthcoming from an English expert of standing. He said there was much misapprehension in the public mind as regards color manufacture, and very general idea that the whole thing depended upon secret processes. There was, however, a very large range of dyes in the actual formation of which no essential difficulty occurred, and the recipes for the manufacture of these would not be of very special value.

The reason why these had not been made previously in this country was not a lack of knowledge as to the formation of the dye itself, but a lack of experience in the economical preparation of the more or less intermediate materials from which the dyes were prepared, and unless, therefore, the recipes in question included a knowledge of these facts, they would not be of much benefit to Great Britain.

Importance of Experience and Plant.

On the other hand, without doubt there were many important coloring matters, the details of the preparation of which, possessed only by the Germans, are essential to their economic large-scale manufacture. A knowledge of these facts would materially benefit English factories. A recipe, however, might mean little without the experience, which often had to be hard-earned, of the working of such processes on the large scale, and again, a very important factor with the manufacture of some special dyes was the plant that had to be employed—not only as to its form, but the special materials from which it had to be constructed. Prof. Perkin continued:

"It is unwise to jump to any conclusion as to the importance of recipes obtained in this peculiar manner, and in any case it would be quire ridiculous to infer that their possession will bring our color industries to the level of those in Germany. Should the matter really be of the importance it is assumed to be, it can do little more than act as a temporary help to our industries in case the knowledge is, as is suggested, to be shared out by our Government to them. It is not by the purchase of recipes abstracted from German factories that we are likely to recover our share in this important industry. The matter goes much deeper than this, and we can not hope to attain in as many months to that perfection which the Germans by patient study have taken nearly 40 years to accomplish.

"While there has been much criticism as to the efforts now being made to recover our lost position in the dye industry, in my opinion the larger manufacturers at least are doing almost all that is possible to effect this object. The main drawback they have to face is the lack not only of chemists in general, but more especially of those who have had any experience in color chemistry, and this is not to be wondered at, because until very recently, among all the educational establishments in the country, the Leeds University was the only one that offered any systematic instruction in this subject."

The burnt-green or apple-green color that was mentioned in the newspaper's original article is reported to be known as guiznets, or "guigennots," a brilliant green pigment, very difficult to produce in the proper shade. Indeed, it is said that that dye has never been produced economically in commercial quantities—not even in Germany.

In regard to the post-war demand for dyes it is of particular interest to note certain statements in the recent annual report for 1917 of Levinstein (Ltd.). This firm, in addition to a factory at Blackley, Manchester, where considerably more than 100 organic products which were never before manufactured in England are now being made on a large scale, is operating the indigo factory at Ellesmere Port, near Liverpool, formerly owned by a German firm. It states:

"The peace-time requirements of the textiles of this country are very different from the war-time requirements. At present the greater part of the textile industries is engaged on the production of military fabrics requiring large quantities of a comparatively small number of dyestuffs. In peace time the requirements are much more varied and consequently more difficult to meet, as a greater range of dyestuffs is then required. To manufacture the same weight of a greater range of dyestuffs needs much more plant than when as at present production is concentrated on fewer types. * * * For our Nation to be left at the mercy of Germany for its dyes at the conclusion of hostilities means that our textile trades will be placed in serious jeopardy.

Present Needs of Industry.

"No policy of free trade or tariff reform will provide our manufacturers and users with dyes if the plant does not exist and the materials can not be produced in this country in sufficient quantity to meet demands when they arise. To-day Germany alone possesses the amount of plant necessary to produce the bulk of these all-essential commodities."

They therefore urge the Government to give the necessary financial assistance and special priority for the erection of plant. Speaking of the steps already taken by the British Government, they say the amalgamation and pooling of resources, research, and knowledge, originally proposed, has so far not been achieved. The investment of £2,000,000 in British Dyes (Ltd.) has not solved the problem of obtaining adequate supplies of British-made dyes.

Some 15 months ago a joint committee of the dye makers and dye users drew up a list of the essential dyes—said to be 400 in number—that are required for the maintenance of the British textile trades, but no organized effort of a national character in the way of facilities for obtaining steel and other structural material for plant, raw material for the dyes, labor, and capital, has yet been made in the United Kingdom up to the present time.

Manufacture of Explosives from Aromatic Compounds

The ordinary practice of manufacturing explosives from aromatic compounds, notably from phenol and from toluene, is based upon treatment with nitric acid and sulfuric acid.

R. H. Twining and R. W. G. Wyckoff, of Geneva, N. Y. (Amer. Pat. 1,242,900, of Oct. 9, 1917), claim that they produce compounds of powerful explosive properties by simply fusing various aromatic substances with sodium nitrate or nitrite. Such substances are of necessity stable and non-volatile at the fusing temperatures of the alkaline salts ($NaNO_2$, 271°C.; $NaNO_3$, 315°C.).

The reaction has been carried out with sulfonates, benzoic acid and phthalic acids. Typical mixtures for fusion are 25 parts of $C_6H_5SO_3Na$ and 75 parts of $NaNO_3$; 18 parts of C_6H_5COOH and 82 parts of $NaNO_2$.

The formation of polynitroso and polynitro compounds is assumed, in harmony with the following equations:

$$C_6H_5SO_3Na + 5NaNO_2 = C_6(NO)_5.SO_3Na + 5NaOH$$
$$C_6H_5SO_3Na + 5NaNO_3 = C_6(NO_2)_5.SO_3Na + 5NaOH$$

The resultant products are described as explosive compounds of great power, incapable of being exploded by shock, even by hammering on an anvil or by pressure, but capable of being detonated by mercury fulminate or other detonators.

It would appear, however, as if these products would be far from rivaling the existing high explosives, such as picric acid and TNT. In the instances shown above by the equations, the final products contain inert matter to the extent of 58% in the case of the nitrite, and 50% in the case of the nitrate.

Manufacture of b-Naphthol Benzoate

Recent improvements in the manufacture of b-naphthol benzoate have been perfected by G. Blieberger, of New York, and the rights are assigned to the Anthony-Hammond Chemical Works, also of New York (Am. Pat. 1,254,970, of Jan. 29, 1918).

The benzoyl chloride used for the purpose is prepared by heating together in a steam-jacketed, enameled kettle, 100 parts of benzoic acid and 70 parts of phosphorus trichloride or pentachloride. The temperature is maintained at a point slightly below the boiling point of the chloride. After completion of the reaction, the benzoyl chloride produced is purified by distillation from a vacuum still.

In reacting upon b-naphthol, 155 parts of benzoyl chloride are required for 100 parts of the naphthol. The latter is introduced into a kettle provided with a reflux condenser, and heated nearly to 198°, the boiling point of the chloride. Under constant stirring the benzoyl chloride is allowed to drop gradually upon the naphthol and combination takes place rapidly. Fumes of hydrochloride acid are conducted from the condenser to a flue.

The product is allowed to cool. It is then taken out of the kettle, placed in water and washed. After washing it is allowed to settle and the water is decanted or drawn off.

The b-naphthol benzoate is next dissolved in warm alcohol, filtered through pure animal charcoal, and allowed to cool, this cooling step causing crystallization. It is then separated by filtering through cloth and is finally dried, and thus becomes a commercial product.

The method is claimed to give nearly a theoretical yield and is unaccompanied by any loss of benzoyl chloride.

A New Method of Producing the Leuco Derivatives of Vat Dyestuffs

The customary method of reducing indigo, the indigoids and the anthracene vat dyestuffs to the soluble, leuco form for the purpose of dyeing is to use sodium hydrosulfite, or, in some cases, zinc or ferrous salts with lime. André Brochet, of Paris, France, has devised a process (Amer. Pat. 1,247,927, of Nov. 27, 1917) based upon the use of hydrogen in the presence of catalyzer, such as platinum, nickel, copper and other metals, or various oxides. The dyestuff to be reduced is suspended with the catalyzer in an alkaline solution which is kept in violent agitation while hydrogen bubbles through the liquid. Pressure favors the reaction.

The following is a description by way of example of the manner in which the reduction of indigo can be effected:

Twenty grams of synthetic indigo and 10 grams of reduced nickel are mixed with 1 liter of water containing 10 to 20 grams of caustic soda, at a temperature of about 60 to 80° C.

The agitating apparatus containing the mixture is connected to an apparatus capable of supplying hydrogen and after displacement of the air, it will be found that the hydrogen is rapidly absorbed under the influence of the agitation.

The indigo white which is formed, enters into solution. When the reduction is completed, the nickel is allowed to settle, and the brownish yellow liquid is drawn off and is ready for use by the dyer.

The improved process is applicable in the same way as indigo, to thio-indigo and to derivatives of indigo and the thio-indigo, to vat dyestuffs such as the indanthrenes, &c., and generally to dyestuffs yielding leuco-derivatives under the action of reducing agents.

Instead of nickel other catalytic metals act with different degrees of effectiveness. The speed of the reaction depends on the proportion of catalyzer used.

Several pieces of apparatus may be connected in series, and the gas and the liquid containing the catalyzer may be caused to travel in opposite directions through them.

The improved process has the advantage of being easily applicable with gaseous mixtures containing hydrogen, for instance, water-gas.

It has over the processes at present in use, the advantage of allowing the economical production of concentrated solutions of leuco-derivatives free from impurities and mineral salts.

A Beehive Coke-Oven with By-Product Recovery

There have been various attempts to modify the construction of the beehive coke oven so as to render it less wasteful, none of which have proved to be of distinct value.

M. Marshall, of Port Coquitlam, British Columbia (Amer. Pat. 1,248,883, of Dec. 4, 1917), has recently devised an oven which aims to recover the major part of the solid and liquid by-products.

It retains the customary dome shape of the ordinary beehive oven. The floor slopes conically to a large grated aperture in the center, connecting with the condensing and scrubbing systems. The conical space above is filled with gravel or broken stone. Above this is a layer of fire brick with frequent openings. It forms the floor proper upon which the charge of coal rests. This is introduced through an opening in the top of the oven.

Drafts are so arranged that the charge is kindled and the upper surface is brought to a bright glow by means of air admitted from below. An uptake flue in the upper part of the oven serving as an exit for the products of combustion and distillation at the beginning, is then closed, and by means of a rotary pump air and steam are forced through the charge from above. As a result the volatile matter released passes downward, through the firebrick floor, and through the gravel beneath to the pipe leading to the condensers.

There is apparently no effort made to recover gas, and the gas would have a very limited thermal value. It is claimed, however, that the ammonia and the tar are both recovered in satisfactory amounts, and that the coke obtained is of a quality superior to that furnished by the ordinary beehive type of oven.

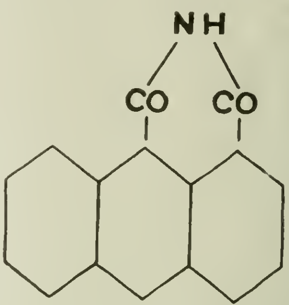
New Dye Manufacturers.

With a capital of $150,000 the Croton Color and Chemical Co. has been incorporated at Croton, Westchester County, N. Y., to manufacture aniline dyes. The incorporators are Paul P. Ihrig, Edward R. Vollmer and Frank C. Schmitz.

A New Vat Dye

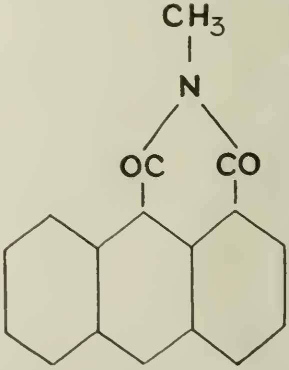
M. Kardos, of Charlottenburg, and Paul Nawiasky, of Ludwigshaven-on-the-Rhine, Germany, assignors to the Badische Anilin & Soda-Fabrik, describe (Amer. Pat. 1,253,252, of Jan. 15, 1918) a new class of vat dyes of interesting properties.

Dr. Kardos, in a patent issued a year ago (Amer. Pat. 1,216,134) showed that a green vat coloring matter can be secured by fusing with caustic potash at 200° to 230°C. anthracene 1.9—dicarboxylic acid imide. This compound:



is derived from aceanthrene quinone oxime, which, in turn, results from the action of hydroxylamine on aceanthrene quinone.

In the patent just issued the reaction with the caustic alkali is extended to derivatives of the above compound containing hydroxyl or a hydrocarbon radical in the imide group. More specifically use is made of the methyl-imide, obtained by the action of methyl-amine, $NH_2.CH_3$, on the anhydride of anthracene—1.9—dicarboxylic acid. The formula is:



To obtain the dye, introduce 3½ parts of the imide into 17 parts of molten potassium hydrate, while maintaining a temperature of about 210° C. and continue stirring for some time at this temperature. Then take up the melt with water, pass air through the liquid until the hydro-compound of the coloring matter has been oxidized and complete the precipitation, if necessary, by means of common salt. Filter off the coloring matter, wash it with hot water and alcohol and dry it. If desired, it can be still further purified by extraction with boiling glacial acetic acid. It yields a red-brown solution in concentrated sulfuric acid and from a red-violet vat colors cotton red-violet shades which, in the air, and more especially upon treatment with boiling soap solution, are converted into shades of a beautiful blue-green, which possess an excellent fastness against the action of chlorine.

In a similar manner analogous coloring matters can be obtained from the phenylimide of anthracene-1.9-dicarboxylic acid (obtainable from aniline and anthracene-1.9-dicarboxylic acid anhydride) and from the hydroximide (obtainable from hydroxylamine and anthracene-1.9-dicarboxylic acid anhydride).

Similar results can be secured by methylating the dye obtained from the unsubstituted imide. The following are the directions:

Place in a reflux apparatus 200 parts of water and 2 parts of the coloring matter obtainable by heating 1 part of anthracene-1.9-dicarboxylic acid imide with 5 parts of caustic alkali and a small quantity of water at from 200° to 230° C. until the formation of the coloring matter is complete, which coloring matter has been obtained in a state of fine division by precipitation from a sulfuric acid solution. Then add 7 parts of potassium carbonate and 10 parts of methyl iodide, and boil the mixture for 10 hours, and afterward filter off and work up. The coloring matter obtained possesses a tinge of green somewhat more bluish than that of the initial material, and it is also fast against the action of chlorine.

In a similar manner the same initial coloring matter can be treated with di-methyl-sulfate, or with the methyl-ester of toluene-sulfonic acid in the presence of caustic alkali, preferably at the temperature of from 60-80° C.

Boil together for 3 hours in a reflux apparatus, 2 parts of calcined soda, 2 parts of the methyl-ester of para-toluene-sulfonic acid, 120 parts of nitrobenzene, and 2 parts of the initial coloring matter referred to above. When the mixture is cold, filter off the product, and free it from nitrobenzene, and from impurities which are soluble in water. The coloring matter, when dry, is a crystalline powder and appears identical with the coloring matter obtainable from the methyl-imide of anthracene-1.9-dicarboxylic acid as described above.

In this example the nitrobenzene can be replaced by trichloro-benzene, or nephathlene.

As compared with the non-methylated dye, the shades of green obtained are of a more bluish tint. The fastness to chlorine is also increased.

The method of dyeing is identical with that used for the indanthrene and other standard vat colors.

New Phenolic Bodies for Use in Tanning

A. Schmidt and A. Andres of Ludwigshaven, Germany, assignors to the Badische Anilin—u. Soda-Fabrik (Am. Pat. 1,254,364, of January 22, 1918), have invented a new tanning material, the sulfonated condensation product of two or more molicules of phenol joined together by acetaldehyde.

The new compound is a free acid, non-crystalline and very soluble in water.

Directions for its preparation are as follows:

Shake together for some time, 94 parts of phenol, 22 parts of paraldehyde, and a small quantity of concentrated sulfuric acid. As reaction takes place heat is evolved, and care should be taken that the temperature does not rise above 90° C. When the reaction is complete, add 100 parts of 97% sulfuric acid and stir, while warming gently, until the reaction product is soluble in water.

For the purpose of tanning, take a concentrated solution of this compound, partially neutralize it with caustic soda solution and then dilute it with water until a solution of 2½° Baumé is obtained. Then add ten grams of common salt to each liter of this solution and employ it for tanning. Leather is obtained which, after being treated with fat, is of good quality and possesses a good resistance to tearing.

Formulas for German Dyes

There has been no little space devoted in the press of late to the statement that somebody in Switzerland had secured possession of over 250 recipes for the manufacture of important German dyes, and that the same had been placed in the hands of color producers.

Many are under the belief that the manufacture of artificial dyes is based upon methods which are carefully kept secret by the German makers. This is, however, far from the case. As a rule, all essential features are carefully protected by patent claims, the details of which are available to the public. Several thousand patents for artificial colors have been issued by the United States Patent Office, chiefly to German inventors, and a printed copy of any patent can be obtained for five cents.

While apparently, and technically, such a patent should reveal all that is needed for an intelligent chemist to reproduce the inventor's results, as a matter of fact the great majority are so skillfully composed and worded that it is by no means an easy matter to ascertain from their contents how to make a given dye.

In the first place there is no mention by name, in a patent, of the color or colors known to the trade, which are placed under protection. While this circumstance offers certain difficulties to the tyro in dyestuff production, it is a matter of slight concern to the large companies engaged in this branch. All new colors are promptly subjected to a most careful laboratory examination, and the relations to patents are fully established. Investigations from the scientific standpoint are also made in the laboratories of universities and technical schools, and gradually a certain literature is created in connection with a color of prominence.

From neither of these sources, however, comes the exact information as to the method in practical use by a company for the most economical production by it, on a large scale, of a given dye, nominally associated with a published patent. The latter may be very broad in its terms, covering several classes of reactions, and the use of numerous materials of closely allied nature. Thus a patent may specify, for the production of a certain class of colors, the use of aromatic amines or their homologues or derivatives. Certain illustrative examples may be given. They may contain no allusion to the actual coal-tar compound employed in making the dye in question, or the chemicals with which it reacts. There are scores or hundreds of possibilities covered by the working of the patent. An exhaustive analytical study may throw more or less light upon the question of the coal-tar intermediates employed, and yet give no indication as to the chemicals used for oxidation, reduction, condensation, etc.

Again, the question of materials may be comparatively simple, and the requisite information may be clearly given in the patent. The latter may fail, however, to furnish the needed data upon relative quantities, time required, temperatures to be maintained, and other data of a physical nature.

It is highly probable that the "recipes" secured in Switzerland refer to the accumulated experience in this latter field, concerning the production of staple dyes, which may have been gained through a long series of years by some one of the German color firms.

In regard to the older dyes, the triphenylmethane colors, most of the azo colors, the eosin class, etc., chemists now know pretty accurately just what intermediates are employed and in what quantities. It is, however, inevitable that any firm, engaged for a long time in the production, has perfected numerous minor details of treatment, which result in a lower cost of production or a more perfect adaptation to specific demands on the part of consumers.

The possession of such knowledge is not indispensable, in the building up of the dyestuff industry in another country. The essential tinctorial values of the overwhelming majority of standard, staple dyes can be duplicated, in this land for example, without great difficulty. Quick-witted American chemists would rapidly improve upon known processes in this field, as they do in others,

It is in the coming contest for holding the domestic market, and for gaining foreign markets, that the possession of such detailed knowledge as is outlined above would prove of great value. More or less information of this character is constantly being secured by American manufacturers of colors as they engage chemists of experience in foreign dye works (Swiss in most cases), each of whom possess a tolerable range of familiarity with a limited number of colors. Not infrequently such chemists are restricted by formal contract provisions from communicating information gained during connection with a given firm. Despite such provisions, the information is bound to become eventually known.

A year ago there was a chemist in Switzerland who had been for a number of years at the head of the French factory of a leading German color company. After the works had been commandeered by the French government and he was retired, he was quite ready to consider an American engagement, based upon his intimate knowledge of the manufacture of a large variety of dyes. It is possible that his repertory forms the basis of the statements referred to above.

German Patents

Active use is now being made in England of the right to employ German patents for the manufacture of coal tar colors. The leading company, British Dyes, Ltd., has applied for permission to produce lyes covered by 77 patents. These latter concern chiefly vat dyes obtained from anthraquinone derivatives, but include also a number of important azo colors, as well as sulfonic dyes in other groups, especially those producing black, brown and blue shades.

In this country regulations have been formulated by the Federal Trade Commission under which patents owned by enemy aliens can be licensed for manufacture by American citizens.

These regulations issued Oct. 30, follow the law closely in safeguarding the interests of patent owners, who must be reimbursed for the use of their inventions, and provide that licenses will be issued only where the interest of the public demands it, to supply a demand not now being met. The licensee must prove his ability to make the article.

Licenses are to be granted for the life of the patent and not merely for the duration of the war, and this is in direct acquiescence to an objection proposed by the dye interests that it would be prohibitive to have to go to the expense of installing costly machinery if they would have to surrender rights to make the dyes after the war. Exclusive licenses are not to be granted to individual firms. The licensee will be required to file with the Federal Trade Commission a semi-annual report of business done.

The use of trade-marks, copyrighted labels and similar trade devices will be granted in exceptional circumstances in connection with the use of the patents.

When the commission will issue licenses for manufacture of articles patented by enemy aliens or their allies probably will depend on the time required for American producers to meet the license requirements.

C. H. McDonald of Wisconsin, Chairman of the Board of Review of the Federal Trade Commission, will have charge of administering the regulations, assisted by Edward S. Rogers of Chicago and Francis J. Phelps of Washington as advisers.

Steps are being taken by our color manufacturers to secure licenses for the production of some much-needed dyes, especially the indanthrenes and other allied vat dyes.

The chief interest centers, however, about the manufacture of synthetic dyes and especially of salvarsan.

There have been many conferences between the Federal Trade Commission and prominent chemists and physicians in regard to the conditions under which permits will be issued. It is highly probable that the Commission will maintain a strict control over output, distribution and price, and that, in the case of synthetic drugs, a certain proportion will be available for military and public health needs.

In the case of artificial colors it would seem to be a matter of prime importance that our manufacturers become familiar as soon as possible with the details of the production of a group of valuable dyes, chiefly sulfur and anthracene colors, the patents of which expire during the next few years. Under existing conditions the preliminary experience can be gained at slight cost. When peace returns, and when a little later the manufacture is free to all concerned, it will be comparatively easy to maintain the output on a basis of cost of production low enough to meet foreign competition.

It is not to be forgotten, also, that the broader our grasp of knowledge of varying operations, the stronger will be our hold on the general situation, and our ability to lower costs of manufacture so as to effectively ensure the continuance of the domestic output of individual products.

One great source of power in a German dyestuff company is the ability to concentrate the experience of a large group of talented chemists on any current problem. Each one contributes from his own special field a helpful idea and aids in simplifying the final solution.

For this reason it is eminently desirable that the American coal tar chemical industry should utilize the present opportunity to make as large a circle of chemists as possible thoroughly intimate, by practice, with all the recent progress in branches which have hitherto been completely closed to us.

Much interest attaches to the recent announcement by Dr. Flexner before the National Academy of Science, that he has obtained a substitute for salversan, equally effective, but costing one-fiftieth of the current price of the synthetic drug.

The manufacture of the latter has now been established in this country by the American representative of the German firm owning the patent. Whatever may be the outcome of Dr. Flexner's discovery, it seems certain that we will have before long a fairly adequate domestic supply of salvarsan, available, however, at a high price. It is authoritatively stated that the drug can be sold with profit at $1.00 per unit, as compared with $25 which has been exacted of American consumers.

Some 20,000 valid patents are affected by the new regulations.

Electrochemical Synthesis of Aromatic Hydrocarbons

At the meeting of the American Electrochemical Society, held at Pittsburgh Oct. 3, Louis B. Cherry described the results obtained so far in exposing mixtures of methane or hydrogen and some of the heavier hydrocarbons of petroleum to the action of high-frequency currents. Experiments have been conducted in systems of pipes, one inch in diameter and 10 feet in length. Each pipe contains a fine platinum wire passing through the center and connected with a high-frequency coil conveying a current of over 100,000 volts. As a result, a silent electric discharge alternates back and forth between the central electrode and the pipe. These treatment pipes are heated by induction, being wound with copper cable. Natural gas and vapors of kerosene (42.5° Bé.) were passed through the pipes under ordinary pressure and under high pressure. It was found that without resorting to additional pressure, 78 per cent. of the kerosene could be converted into gasoline of 65° Bé. No carbon is deposited in connection with the conversion at temperatures below 480° C.

Plans are now under way to put the process into economic operation by attaching the apparatus to petroleum refineries in regions where natural gas is available. During distillation the proper fractions of oil vapors would be delivered into the treatment pipes or chambers.

Naturally it has been considered possible that modifications of the process might permit of the formation of aromatic hydrocarbons. Preliminary experiments in this connection indicate favorable results. Oil vapors, without an admixture of natural gas, under a pressure of 5½ atmospheres and at a temperature of 538° C., when passed through the apparatus, yield a distillate consisting largely of benzone and toluene. These experiments are being continued and may possibly result in opening up a new source of toluene which will be extremely welcome at present.

Mr. Cherry assumes that the ionizing effect of the heated tubes, combined with the effect of the high-frequency current, brings about a double reaction, disorganizing the gases and oil vapors and simultaneously reorganizing the molecules without causing any separation of carbon or other elements.

German Dyestuff Companies

We have had occasion to refer to the extensive preparations made by the great German dyestuff companies to reconquer, on the return of peace, the territory now commercially lost to them. The six largest companies pooled their interests for this campaign a year ago, and will act as a unit. They have all announced notable increases of capital. In the cases of the "Badische," "Bayer" and the Höchst Farbwerke, the individual increases are from about $13,500,000 to $22,500,000. The German Government has practically promised them subventions, if necessary, to enable them to win back the lost trade.

One of the important factors in the situation, the works of the Griesheim Company near Frankfort, were practically wiped out of existence on Nov. 22, by a terrific explosion. It is considered impossible to reconstruct the works during the war. Like all the other great coal-tar chemical works, the company at Griesheim was devoting its energies chiefly to the production of munitions. Its loss will very materially affect the current supply for the German army.

London advices give the following data on the extent of the operations of this plant and picture conditions quite similar to those existing in the plants of the "Badische" and other leading companies:

"The explosion caused the complete destruction of one of the greatest munition factories in the world. Germany suffered a disaster comparable to a very serious military defeat in its effect on the war.

"The Griesheim factory consisted of a group of buildings covering over fifty-four acres. Before the war it ranked as fourth in importance among great German chemical works, and was flourishing, the company paying a pre-war dividend of 14 per cent. and being worth as a going concern well over 60,000,000 marks.

"Its commanding position in the chemical world rested not only on its huge output, but also on the extensive variety of its manufactures. These comprised, among other things, aniline dyes of every description, nitric, sulfuric, and other acids, phosphorus and alkali, with liquid chlorine, hydrogen and oxygen as important by-products.

"Moreover, it was of prime importance as a source of synthetic nitrates, and its splendidly organized research laboratory enabled it to play a leading part in the production of poison gas and other forms of frightfulness which Germany has introduced in the course of the war.

"The Greisheim concern has been producing saltpeter for the manufacture of black powder at the rate of 1,000 tons daily, and it was reputed to be the only factory turning out this article. To such an extent had its already impressive output of nitrate and sulfuric acid been developed that it supplied the whole demand of five nitroglycerin and dynamite factories, as well as of two powder works, including that of Rottweil, one of the most important in Germany.

"Another explosive which was manufactured in large quantities was tonite, through its facilities for making synthetic phenol, and consequently picric acid, from which acid this explosive is derived.

"Another circumstance of interest is that this factory supplied quantities of electrolytic hydrogen for the inflation of Zeppelins, and possesed by way of a reserve three gasometers with a total capacity of over 300,000 cubic feet. The electrolytic plant was further utilized to produce asphyxiating gas and lachrymatory and poisonous shells. In fact, it is the greatest center of this manufacture in Germany, and in 1916 the output of poison gas reached nearly 600,000 cubic feet daily.

"Every concern in Germany is affected both by the cutting off of supplies which many of them formerly drew from Greisheim and by the necessity of making the loss of these supplies good from plans already working to the maximum. The death of scores of trained workmen and specialists in the factory itself and the dwellings within its confines will make the task of coping with this deficit all the more difficult."

The corporate name of this company is "Chemische Fabrik Griesheim-Elektron." Numerous synthetic dyes have been discovered in its laboratories and placed upon a manufacturing basis.

The Physical Basis of Color

The fundamental reasons for the phenomena of color are constantly being subjected to investigation.

In a recent issue of the "Färberzeitung" the connection between size of molecule and tinctorial results is made the subject of study. The following paragraph summarizes the conclusions:

"Whtenever a dyestuff is affected by light, the cause is to be found in the absorption of a part of the light rays by the dyestuff, resulting in an oscillation of the molecule. A dyestuff which produces a bright fast color is characterized by a molecule which is not greatly influenced by the amplitude of vibration of the penetrating waves of light, consequently the intensity of the transmitted or diffused and the absorbed light waves is only slightly diminished. In the case of dull and fugitive colors the amplitude of the chemically

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS.*

PART XIII

Trinitrotoluene.

Custis reports the following experiments on trinitrotoluene. The compound was placed in a capillary tube made of quartz. This tube was kept in the path of the rays emanating from an iron arc which was placed 1.5 centimeters from the tube. After six hours' exposure the product was examined. It had turned a dark brown and had a melting-point of 79.06°.

Samples of trinitrotoluene, melting-point 80.47°, were placed, one in a capillary tube made of quartz, and another in a capillary tube made of glass. These tubes, together, were placed on a table 7 centimeters from a mercury quartz lamp. The heating effect of the lamp on the tubes was greatly reduced by employing a mechanical blower, so arranged as to drive a constant stream of air over the tubes. The temperature indicated by the thermometer was 30° at the beginning and 40° at the end of a three-hour period. After an exposure of the above duration the samples were examined. There appeared to be no darkening of the crystals in either tube. The melting-point of both specimens was found to be the same, namely 80.21°. This identity in the change of melting-point in samples contained in glass and quartz, and exposed to the rays from a mercury quartz light, seemed surprising. The experiments indicate that artificial light materially affects trinitrotoluene, and that the long ultra violet rays (i.e. those which can pass through 7 centimeters of air) have little, if any, greater effect than the "visible" rays from a mercury quartz arc. The change in this nitro compound is stated to be due to oxidation.

Esterification by Ultra Violet Light.

Stoermer and *Ladewig* (Ber. 1914, *47*, 1803,) have accidentally discovered that, when alcoholic solutions of trans-cyclopentane 1:2-dicarboxylic acid are exposed to ultra violet light (Uviol lamp) conversion into mono- and di-esters occurs. The expected transformation into the cis-modifications did not occur. Benzoic acid is also esterified under these conditions (30 per cent. in 8 days) and the reaction is still further promoted by the presence of a trace of hydrochloric acid (56 per cent. in 8 days). Cinnamic acid is scarcely affected without the addition of a trace of hydrochloric acid, but the yield of ester may then reach 37 per cent. in 8 days. The methyl esters of these acids were thus produced.

Oxidation of Aromatic Hydrocarbons.

The fact that the most easily isolable products of the autoxidation in light, of benzene homologues, are carboxy-acids is attibuted by *Suida* (Monatsh, 1912, *33*, 1255) to the relative instability of the intermediate products. The most satisfactory source of light was a quartz lamp, used at a distance of about 10 centimetres from the specimen of substance. The velocity of the first stage of the oxidation could be approximately measured by the amount of peroxide formation; this was estimated by the action on a solution of potassium iodide acidified with dilute sulphuric acid with titration of the liberated iodine some hours afterwards. The parallel formation of carboxylic acids was estimated previously by titration with N/30-potassium hydroxide solution; it appears that the amount of acid formed cannot be entirely due to the decomposition of the peroxide.

The results indicate that pure benzene is practically passive but that the presence of thiophen causes peroxide formation. Methyl substituted benzenes undergo autoxidation when illuminated, and the action is accelerated by the presence of small quantities of nitrobenzene or of one of the nitrotoluenes. The oxidation of xylene occurs more than twice as rapidly as that of the toluenes, and p-xylene, oxidizes more rapidly than the ortho-isomeride. The oxidation of 4-nitro-m-xylene under the influence of light resembles that of p-nitrotoluene, but is feebler.

Organic Peroxides.

In endeavoring to oxidize benzaldehyde in the presence of oxygen, directly to benzoyl hydroperoxide, *Suida* (Ber. 1914, *47*, 471), used a Heraeus quartz lamp. A current of oxygen was passed through benzaldehyde in petroleum ether and the solution was exposed at a distance of about 2 cm. from the burner. The vessel in which the benzaldehyde was exposed was cooled with ice. During an exposure of 6 hours a considerable quantity of benzoic acid formed, together with small quantities of a peroxide body. On cooling the vessel by means of solid carbon dioxide and ether the formation of the peroxide was much increased. A white deposit was slowly obtained which had strong oxidizing properties and a pungent odor. The peroxide substance could not be isolated readily on account of rapid conversion into benzoic acid. At the same temperature, but with the exclusion of light there was no indication of formation of the peroxide body.

Benzaldehydephenylhydrazone does not redden at all, even on prolonged exposure to the air, if light is excluded. (Chattaway, J. Chem. Soc. Trans. *89*, 1906, 463). In light, its color alters in a remarkable way; in diffused light, reddening takes place slowly, but in sunlight the change becomes very noticeable in a few minutes and the color quickly deepens until after a few hours a maximum intensity is reached, when the crystals have a brilliant scarlet color resembling that of azobenzene. The light from an electric arc playing between iron poles, which is extremely rich in ultra violet rays, also brings about the change, the velocity of which falls off in the ordinary way as the distance from the arc is increased. Exposed in a quartz tube at a distance of five cm. the change was about as rapid as in direct winter sunlight. The transformation, however, appears not to be due to ultra violet rays, as its rate is not affected by interposing a sheet of ordinary crown glass.

Reduction of Ketones.

The reduction of an aromatic ketone in a perfectly neutral medium does not proceed any further than to the pinacone, according to *Boeseken* and *Cohen* (Proc. K. Akad. Wetensch, Amsterdam, 1914, 17, 849; J. Chem. Soc., 1915, Abs. 108, ii, 37). A series of ketones dissolved in a great variety of anhydrous alcohols and a few other substances have been exposed to the light of a mercury lamp; in all cases where reduction occurs not a trace of the hydrol is formed, the ketones being quantitatively changed to the pinacones. The addition of sodium ethoxide to the alcoholic solution results in the formation of the hydrols, as is to be expected. The conclusion is reached that in the reduction of aromatic ketones the hydrogen unites exclusively with the oxygen; the resulting half-pinacone polymerises to the pinacone, and the latter, in the presence of hydroxyl ions is transformed into an equal molecular mixture of the ketone and the hydroxyl.

Quinine.

A study of the reaction between chromic acid and quinine in light has been made by *Goldberg* (J. Chem. Soc., 1906, Abs., ii, 514) whose results seemed to indicate that the velocity was dependent on the quantity of light absorbed by the chromic acid. *Luther* and *Forbes* (J. Amer. Chem. Soc., 1909, 770) have found, however, by means of monochromatic light that the quinine is the substance which is sensitive to light, while the chromic acid only acts as an indifferent light filter, absorbing a part of the light and converting it into heat. Determinations of the initial velocities of the reactions induced in solutions by monochromatic light have been made, and the quantities of light absorbed by the quinine and chromic acid have been calculated from measurements of extinction coefficients. The concentrations of the reacting substances, the intensity of the incident light, and the wave-lengths of the light were varied, one at a time, in successive experiments. The source of light was a uviol mercury vapor lamp, and a series of light filters were employed. It was found in preliminary experiments that the total reaction velocity was proportional to the concentration of the hydrogen ion. The photochemical reaction is exactly the difference between the total reaction and the spontaneous reaction of the same mixture in the dark, and the combined effect of two rays is additive. The speed of the photochemical reaction is proportional to the quantity of light of given wave-length absorbed by the quinine alone unless the concentration of the chromic acid is very small. It is probable that the reaction takes place in two stages: (1) the formation of sensitized quinine with a velocity proportional only to the light absorption, and (2) a reaction in ordinary sense, between this product and chromic acid with a velocity proportional to the concentration of the chromic and sulphuric acids.

Nicotine and Pyridine.

The effect of ultra violet rays on nicotine and pyridine have been studied by *Custis* (J. Frank. Inst. 1917, 878), who found that ultra violet radiation produces a change in nicotine solutions. A one-tenth per cent. solution of nicotine when exposed in a quartz flask at 5 centimeters from a source of ultra violet light for 15 minutes showed a decided decrease in nicotine content. A 40 per cent. solution of commercial nicotine, when exposed for 30 minutes at 5 centimeters from an iron arc showed an increase in the amount of nicotine present. Custis explains this increase in the second sample on the grounds that commercial nicotine contains impurities in the form of certain oils and it is not unlikely that nicotine was synthesized from these oils.

Turpentine.

Dedichen and *Halse* (U. S. patent 1,253,793, Jan. 15, 1918) expose raw turpentine oil to the action of ultra violet rays while subjecting it to the action of air or oxygen. The oil is then treated with iron chloride to refine and deodorize it and obtain a mixture of α and β-pinenes containing dextro-rotary β-*pinenes*.

Phenyl Vinyl Acetic Acid.

As a representative of the β, λ. ethytenic acids λ phenylvinylacetic acid in benzene solution was exposed to ultra violet light by *Stoermer* and *Stockmann* (Ber., 1914, *47*, 1793). The acid resinified to a considerable degree. Although the allo-form could not be obtained in crystalline form, the crystalline allo-amide was isolated and converted by illumination into the stable variety.

Chlorination of Acetic Acid.

The effect of ultra violet light on the chlorination of acetic acid has been investigated by Custis (J. Frank Inst., 1917, 874). Glacial acetic acid was placed in a quartz flask fitted with a reflux condenser and heated on a steam bath. Chlorine was passed into the flask and subjected to the influence of the rays from an iron arc at a distance of 3 centimeters, giving monochlor acetic acid. The use of red phosphorus as a catalyzer improved the yield. If, however, the flask was placed under the influence of rays from an ordinary projection lantern at about 5 centimeters, the other conditions being the same, no chlor acetic acid was obtained. No results were obtained by passing the chlorine gas through a quartz tube which was illuminated with ultra violet rays before being passed into a non-illuminated flask containing glacial acetic acid.

Custis (J. Frank. Inst., 1917, 875) has also investigated the effect of ultra violet light (iron arc) on the chlorination of benzene and toluene. At room temperature no substitution products were obtained under the influence of the rays from an ordinary projection lantern, but when exposed to ultra violet rays chlorinated products were obtained. Toluene was chlorinated under similar conditions by passing chlorine which had been activated by ultra violet rays before being passed into a non-illuminated flask of toluene. Benzene could not be chlorinated in this manner.

Oil Hardening.

A process of hydrogenating oils involving exposure of the oils as a film on a web carrying catalytic material and at the same time exposing the oil and catalyzer to the rays of an ultra violet light has been proposed by *Walter* (Hydrogenation of Oils, New York, 1914, 34; Seifen. Ztg. 1913, 442). One form of apparatus described by Walter for carrying out this reaction consists of a closed vessel in which is placed a belt or web carrying catalytic material. The belt may be made of asbestos or cotton cloth and may be impregnated with platinum, iridium, nickel or other catalytic material. The belt is carried on rollers, one of which dips into the oil. Catalyzers also may be carried in a container attached to the belt. The ultra violet lamp is located in the closed vessel, thus illuminating the interior.

Utescher (British patent 20,061, Sept. 3, 1912) treats oils with hydrogen in presence of a finely-divided catalytic agent, and at the same time the material is subjected to the action of a silent electric discharge, which it is stated is prevented from coming into actual contact with the fatty substance, the chemically active rays only being utilized. It is also stated that the process may be effected by allowing the rays to impinge on the surface of a catalytic substance which may be used in the form of plates.

Testing Hydrogenated Oils.

Ultra violet light may be used as a qualitative test in some cases for the detection of unhydrogenated oils in hydrogenated oils or fats. A well-hardened hydrogenated oil, such as hardened cottonseed oil of a melting point of about 60° C., is very resistant to the action of ultra violet light, while the cottonseed oil from which it is prepared is quite readily thickened by the effect of the ultra violet waves. Accordingly, a mixture of the two glycerides changes in appearance on exposure to ultra violet light. Many ordinary greases or fats such as soapmakers' tallows and the like are darkened and polymerized on exposure to ultra violet light, while hard fat of the melting point referred to is scarcely visibly changed. An exposure of several hours at a distance of 4 to 8 inches from the burner is recommended.

Gas Analysis.

The application of ultra violet light in the analysis of gases is suggested by *Landau* (Compt. rend., 1912, *155*, 403; J. Chem. Soc., 1912, Abs., *102*, ii. 986). Ethylene is slowly polymerized by light from a mercury lamp of 110 volts, but the action is incomplete even after 134 hours. With a 500-volt mercury lamp, polymerization is complete, both for ethylene and acetylene. Ethane and methane are not affected by ultra violet light, but in the presence of excess of oxygen the former is eventually completely oxidized to carbon dioxide and water. Carbon monoxide in presence of oxygen is also slowly, but completely, oxidized to carbon dioxide. Landau suggests that the analysis of mixtures of hydrogen ethylene, and ethane might be accomplished by the use of ultra violet light.

Carbon Dioxide.

By the action of ultra violet light on dry carbon dioxide, *Chadwick, Ramsbottom* and *Chapman* (Proc. Chem. Soc. 1906, 22, 23) succeeded in partially decomposing the gas into carbon monoxide and oxygen. No determination of ozone was made. With moist carbon dioxide no decomposition occurred. The peculiar influence of water vapor is believed to be due to the action which it exerts on the vibrations of the electrons of the gases.

Ammonia.

Coehn and *Pringent* (Zeitsch. Elektrochem. 1914, 20, 275; J. Chem. Soc. 1914, Abs. *106*, ii, 404) have endeavored to ascertain whether the decomposition of ammonia is complete or whether a determinable amount of ammonia remains undecomposed. Ammonia was sealed up in quartz tubes and exposed to the light of a quartz mercury lamp, and the gas examined after various periods of exposure. It was found that after one hour ammonia was still present, but after six hours ammonia could not be detected by means of Nessler's reagent, thus showing that the decomposition was complete. Weigert (J. Chem. Soc. Abs., 1908, ii, 5) has shown that when a mixture of nitrogen and hydrogen is sensitised by the addition of chlorine, ammonia is formed by ordinary visible light. Coehn and Pringent have passed similar mixtures, dry and damp, through a quartz tube, which passed down the centre of a quartz mercury lamp, and have been unable to show the formation of ammonia even in such small amounts as would give the reaction with Nessler's reagent.

Properties of Phosphorus.

When a strong current of air is drawn through a solution of phosphorus in paraffin, the resultant glow shows a continuous spectrum in the visible region. With the aid of a specially constructed "phosphorescent screen" and an exposure of 95 hours, *Centnerszwer* and *Petrikaln* (Chem. Abs. 1912, 3355; Z. Physik. Chem., 80, 235-40) succeeded in photographing the ultra violet region. They found sharply defined lines and a band in the neighborhood of 3252° A, indications being that this band is composed of separate lines.

Though there is strong absorption in the ultra violet, there were no visible lines or bands. In an investigation of the reported effect of radiations from phosphorus on a photographic plate wrapped in black paper it was found that when the oxidation products were removed as fast as they were formed, the plate was not affected, indicating that the effect was due to some volatile oxidation product, presumably hydrogen peroxide.

Calcium Carbide.

Calcium carbide was exposed to the action of ultra violet rays by Custis (J. Frank. Inst. 1917, 880). There was apparently no reaction as no pressure was built up and the tests for ammonia in the treated product gave negative results.

Chloroplatinic Acids.

A comprehensive study has been made by *Boll* (Ann. Physique, 1914 (ix), 2, 54, 266; J. Chem. Soc., 1915, Abs. *108*, ii, 123) of the photochemical decomposition of chloroplatinic acids in very dilute aqueous solution, and some observations relating to the decomposition of oxalic acid in presence of uranyl nitrate are also described. The progress of the photochemical reaction was determined by measuring the accompanying increase in the electrical conductivity of the solution. In a series of experiments, in which the solutions were exposed to the light rays emitted by a mercury quartz lamp, it was found that the photochemical decomposition of all the chloroplatinic acids proceeds in agreement with the formula for a bimolecular reaction. In all cases the reaction is practically complete, and from the observed differences between the final and initial conductivities it would seem that two molecules of hexa-, penta-, tetra-, di- and mono-chloroplatinic acid give rise respectively to 11, 9, 7, 3 and 1 molecules of hydrochloric acid. The solutions, which are obtained when the photochemical decomposition has run its course, are metastable, and as a general rule deposit a reddish-brown precipitate of platinic hydroxide. Experiments with tetrachloroplatinic acid, in which the solutions were subjected to the influence of monochromatic ultra violet light (λ 2536 and λ 2655) have shown that the reaction velocity is proportional to the intensity of the incident radiation. The photochemical decomposition of the chloroplatinic acids can be made use of in the construction of a chemical actinometer covering a range which extends from the yellow to the extreme ultra violet.

Oxalic Acid.

The experiments relating to the photochemical decomposition of oxalic acid indicate that this reaction is unimolecular, and from the total change in the electrical conductivity Boll (J. Chem. Soc. 1915, Abs. *108*, ii, 123) draws the conclusion that the chemical reaction corresponds with the equation $H_2C_2O_4 + O = 2CO_2 + H_2O$. Uranyl nitrate in the solution acts as a catalyst. In agreement with the observed unimolecular character of the reaction, it is found that the velocity is proportional to the quantity of light absorbed by the solution, and that this proportionality is independent of the concentration of the oxalic acid.

The decomposition of oxalic acid by uranium and its compounds has been investigated by *Landau* (Compt. rend. 1913, 156, 1894) and shown not to be parallel with the radio-activity of the substances used. The lightest and heaviest metal of each of six groups of the periodic table were also tried in the form of nitrates, and of these only chromium and uranium (group VI) proved to be active, uranium being three times as active as chromium. A mercury lamp was used as the source of light.

Mercuric Oxalate.

According to *Winther* a solution of mercuric oxalate completely free from iron would be photochemically inactive. The fact that this conclusion did not agree with Eder's observations (Zeitsch. wiss. Photochem., 1914, 14, 172; J. Chem. Soc., 1915, Abs., 108 ii, 199) has led to a further series of experiments with solutions prepared from carefully purified substances. These experiments show that the photochemical sensitiveness of solutions of mercuric oxalate (mercuric chloride and ammonium oxalate) is not dependent on the presence of traces of ferric salts, but is also exhibited by the pure mercuric compound. The decomposition of the mercuric salt is mainly determined by the ultra violet rays, but comparative observations have shown that the relative activity of the visible rays is increased if the solution contains small quantities of iron.

The precipitation of mercurous chloride from Eder's solution, on exposure to light, reaches a limit when the solution still contains large quantities of mercuric chloride and ammonium oxalate. Comparative experiments by *Winther* and *Howe* (Zeitsch. wiss. Photochem., 1913, 13, 89; J. Chem. Soc. 1914, Abs. *106*, ii, 10) in which equal volumes of the filtrate and of a fresh solution of the same composition were exposed to the influence of light under similar conditions, indicate that the initial photochemical action leads to the formation of some substance which acts as a powerful negative catalyst. The same phenomenon is met with in the case of Eder's solution to which eosin is added. In general, the effect becomes more marked as the intensity of the light increases. If the ultra violet rays are cut off during the preliminary exposure, the photochemical sensitiveness does not disappear. Further, it has been found that there is an appreciable loss of sensitiveness if the eosin solution is insolated before adding to the Eder's solution. The observations seem to show that the anti-catalyst which reduces the photosensitiveness of the solution is a product of the photochemical decomposition of eosin.

Ferrous and Mercuric Chlorides.

The rate of reduction of mercuric chloride by ferrous chloride under different conditions has been examined in some detail by *Winther* (Zeitsch. wiss. Photochem., 1912, *11*, 60). When the concentration of the mercuric chloride is constant and relatively small, the rate is nearly independent of the concentration of the ferrous salt. For a given concentration of the latter, the rate increases at first with the amount of mercuric chloride and then diminishes. The maximum appears to be attained when the two salts are present in equimolar quantities. In the case of solutions containing small quantities of mercuric chloride relatively to ferrous chloride, the sensitiveness increases with the dilution, but this is not the case for solutions containing equimolar quantities. Such solutions do not vary to the same extent when the concentration is changed, and the maximum sensitiveness is shown by solution containing the two salts in 3-molar concentration. The presence or absence of oxygen is without appreciable influence on the equimolar solution, but oxygen reduces the quantity of mercurous chloride obtained when a large excess of ferrous chloride is present. The most active light rays are those of wave-length less than 265 $\mu\mu$, as is shown by comparative experiments in quartz, uviol glass, and ordinary glass vessels.

Iodine.

An apparatus is described by *McLennan* (Proc. Roy. Soc., 1913 (A.), 88, 289-296; J. Chem. Soc., 1913, Abs., ii, 455) by means of which it has been possible to subject iodine vapour to intense illumination by light of wave-length extending from beyond $\lambda = 700$ $\mu\mu$ down to $\lambda = 185$ $\mu\mu$. The apparatus consists of an outer glass illuminating tube of ordinary Cooper-Hewitt type, and an inner tube of clear fused quartz, which is sealed into the former by wax joints. The outer tube is furnished with mercury electrodes, and carries the mercury arc, whilst the inner tube, after the introduction of crystals of iodine, is exhausted and sealed off.

The fluorescence spectrum, which is exhibited by the iodine vapour under these conditions, is characterized by the presence of a large number of narrow bands extending from about $\lambda = 460$ to about $\lambda = 210$ $\mu\mu$. More than eighty such bands have been recognized on the photographic records, and the mean wave-lengths of these are recorded. When the inner quartz tube is replaced by a similar tube of glass, the band spectrum disappears. From this it is inferred that the emission of the banded spectrum is not due to the elevated temperature of the vapour in the tube, but is a true resonance or fluorescence effect. The fact that the glass tube inhibits the banded spectrum indicates further that the exciting light consists of short-waved rays, which are absorbed by the walls of the glass tube. Further observations by McLennan (Proc. Roy. Soc. 1914 (A), *91*, 23; J. Chem. Soc. 1914, Abs. *106*, ii, 829) show that the spectrum is excited at all temperatures between that of the room and 1000°. It is called forth when the wave-length of the exciting light falls between the limits λ 2100 and λ 1800. On the other hand, reasonance spectra cannot be obtained when the iodine vapour is illuminated by light from a mercury arc of wave-length less than that of the green line λ 5460. The investigation of a number of iodine compounds has shown that iodoform and mercuric iodide give a fluorescence spectrum which contains the seven well-marked bands of the iodine fluorescence spectrum between λ 3315 and λ 3175. In addition to the iodine lines, the mercuric iodide spectrum contains a number of specific bands which are absent from the iodine spectrum. With potassium iodide, a fluorescent spectrum is obtained which does not show any of the iodine bands. It consists of two sets of unequally spaced fine lines in the regions between λ 4047 and λ 3340 and between λ 3075 and λ 2940.

Iodides.

It has been observed by *Ross* (J. A. Chem. Soc. 1906, 788) that when a solution of potassium iodide is exposed to ultra violet light (produced by a spark between aluminum terminals) the exposure being made in an open vessel, the amounts of iodine set free, on making exposures for equal intervals of time, varied greatly. When the distance of the solution from the spark was doubled, the rate of decomposition remained almost the same as before. The spark was then made to pass through an atmosphere of oxygen. This was done by placing the terminals in a large bell jar filled with the gas. Under these conditions, the rate of decomposition was found to be very much increased. In replacing the oxygen with carbon dioxide, the amount of decomposition resulting in the same length of time was very small. It therefore became evident that the greater part of the decomposition first obtained was produced, not by the light only, but principally by the action of ozone and the oxides of nitrogen formed by the passage of the spark through air. To determine the effect of the ultra violet light only, the solution was placed in a small shallow dish provided with a quartz cover. The latter was sealed into a rim of hard rubber which was in turn surrounded by an elastic rubber band. This then could be slipped over the top of the dish so as to secure the complete exclusion of any gas. When the dish was now placed underneath the spark, the decomposition resulting represented the total effect of the waves of light given out by the spark. By subtracting from this the effect produced when a thick piece of glass plate was interposed between the spark and the solution, the effect of the ultra violet light alone, or that part of it capable of being absorbed by the glass, was determined. When a photograph of the spectrum given by the spark was taken by means of a spectroscope, it was found that with the thick glass plate interposed between the spark and the spectroscope, all wave-lengths were absorbed below λ 3260. That the decomposition of the iodide, which took place when gases formed by the spark were excluded, was due to the action of the light alone was shown by varying the distance of the solution from the spark. It was now found that the amount of iodine set free varied inversely as the square of the distance, which one would expect if the decomposition is due entirely to the amount of light energy incident upon the solution. The iodides of sodium, lithium, barium, calcium and zinc were found to give results similar to those obtained with potassium iodide.

Ross (J. Am. Chem. Soc., 1906, 786) investigated the reduction of chlorates and bromates by the action of ultra violet light and observed that while solutions of the chlorates and bromates are quite stable in sunlight, they were reduced to quite an extent when acted upon by that part of the ultra violet spectrum capable of being absorbed by glass. It was found that solutions of all chlorates of the same strength were reduced at the same rate, while the same thing was true of the bromates. The rate of reduction of the chlorates, however, differed from that of the bromates. Unlike iodides or ferric salts, varying the strength of either the chlorate or bromate solutions from ½ to 1/50 normal did not produce any appreciable difference in the amount of reduction which took place. In the case of the bromates the amount of salt reduced was less than in the case of the chlorates. Thus, when the strength of any standard bromate solution was varied from 1/2 to 1/100 normal, the amount of bromide formed in every case was equivalent to only 0.25 cc. of a 1/200 normal silver nitrate solution. The amount of chlorate or bromate reduced was found to be exactly proportional to time of exposure. Sugar added to solutions of the chlorates or bromates resulted in an increase in the amount of reduction.

Chlorates, Bromates and Iodates.

The influence of ultra violet light on alkaline salts of acids containing halogen and oxygen has been compared by *Oertel* (Biochem. Zeitsch. 1914, *60*, 480; J. Chem. Soc. 1914, Abs. 106, ii, 321). Under the action of ultra violet light the alkali salts of chlorates, bromates, iodates and periodates in aqueous solution decompose into oxygen and the halogenide, and the reaction is quantitative with a sufficiently long period of illumination. Only a very small decomposition could be observed in the case of the perchlorates. The rate of decomposition in the case of the bromates was greater than that of the iodates, and of the latter greater than that of chlorates. The amount of reaction products formed in a given time increased with increasing concentration of the solution, and the nature of the cation was without influence on the rate of decomposition. The solid substances also undergo decomposition when exposed to light, the chlorates decomposing readily, the bromates less so, the iodates being changed but very slightly.

The action of light of short wave-length on solutions of potassium iodate has been investigated by *Mathews* and *Curtis* (J. Physical Chem., 1914, *18*, 641; J. Chem. Soc. 1914, Abs. 106, ii, 830). Solutions of 0.1N-potassium iodate were placed in a quartz flask and kept at a temperature of 30 by allowing a stream of water at this temperature to flow over them. Light from a mercury vapour lamp was allowed to fall on the flash, when iodine was liberated. The amount of iodine liberated was estimated from time to time by titration with a 0.001N- solution of potassium thiosulphate. The following results are obtained: (1) When the photolysis is carried out in the presence of air, the rate of the reaction slowly decreases with time. (2) Iodine is not liberated when the solution is kept saturated with oxygen in an atmosphere of oxygen. (3) Carbon dioxide greatly increases the rate of photolysis; and (4) the rate of photolysis of potassium iodate in a solution kept saturated with carbon dioxide is linear when the amount of iodine liberated is small compared with the total amount present in the iodate. It is therefore not possible in such circumstances to determine the order of the reaction. It is suggested that the photolysis occurs according to the scheme: $KIO_3 = KI + 3O$ and $5KI + KIO_3 + 6CO_2 + 3H_2O = 6KHCO_3 + 3I_2$; the liberation of oxygen has been experimentally proved. Light accelerates the reaction between potassium iodate, potassium iodide and carbon dioxide, but the reaction is very complex in the presence of light, and has not been quantitatively investigated. A lecture experiment to demonstrate the photochemical activity of light of short wave-lengths is described. To a solution of 0.1 gram of potassium iodate in 500 c.c. of water, 2 c.c. of a 1% solution of potassium iodide and 2 c.c. of starch solution are added. One-half of the solution is placed in a quartz flask, and the residue in a glass flask. The flasks are placed at equal distances from a quartz mercury lamp, and in a few seconds the solution in the quartz flask turns blue, while the other remains quite colorless.

Absorption of Ultra Violet Rays by Ozone.

In an investigation of the transparency of the atmosphere for ultra violet radiation, *Strutt* (Nature 1917, 144) states that the solar spectrum, even when observed from a mountain top, does not extend so far as 2900, which result is attributed to absorption by ozone. Strutt has now photographed the spectrum of a mercury vapor lamp four miles distant and finds that it extends as far as the line 2536 and perhaps further. This line lies near the maximum intensity of the ozone absorption band, and therefore ozone can have nothing to do with the limit of the spectrum in this case. To reconcile the two results it is assumed that there is much less ozone near the earth's surface than at high levels.

Effect of Change in Wave Length.

Bovie (Am. J. Trop. Diseases and Prev. Medicine, 1915, 506) has made an interesting contribution to the subject of the action of light on protoplasm. He states that if the object upon which a wave train falls is capable of resonant vibration and if these vibrations are accompanied by friction the temperature of the object may be raised or the absorbed energy may bring about chemical changes. With constant light intensity, the abiotic action of ultra violet light increases with the vibration frequency. The effect which a slight extension of the solar spectrum might have upon the life is shown by an experiment made by Bovie, who tested the killing power of light of various wave-lengths between 3,000 and 2,500 Angstrom units (sunlight ends at about 2,950 Angstrom units. Bacteria and the spores of various fungi were used. It was found that light of wave-lengths shorter than 2,925 Angstrom units would kill by an exposure of 10 minutes, while for wave-lengths longer than 2,925 Angstrom units the organisms were not killed by an exposure of 120 minutes. A change of wave-length of only 25 Angstrom units was sufficient to cause this great change in the killing power of the light.

Ultra violet light can penetrate the blood-filled skin but a fraction of a millimeter, but if the skin is rendered anemic by pressing out the blood, bacteria can be killed by ultra violet light which has passed 4.25 millimeters of skin. This fact is of importance in connection with the question of the pathological effects of an excess of light. The energy of the light absorbed might cause a decomposition of the substances contained in the blood, and the blood stream would become loaded with protein decomposition products. Hasselbach has shown that ultra violet light of wave-length less than 3,100 Angstrom units causes a decomposition of the red blood corpuscles.

Photodynamic Effects.

There is another phase of the action of light which has great biological interest, a phase which Bovie thinks should be more extensively investigated. This is the so-called "photodynamic effect" of fluorescent substances. Vogel in 1873 showed that when certain fluorescent stains are added to the gelatin of a photographic plate, the plate becomes more sensitive to those colors which these stains absorb.

The silver salts used in sensitizing the photographic plate are normally more sensitive in the violet and ultra violet part of the spectrum than they are in the red and orange part. If, however, a fluorescent stain which absorbs, for example red light, be added to the plate, the sensitiveness of the silver salt to red light will be increased so that it may equal or even exceed the sensitiveness to violet and ultra violet light. In other words, red light acts on silver salts plus a fluorescent substance as ultra violet light does on the silver salts alone. Fluorescent stains are regularly employed in the manufacture of certain orthochromatic plates. It has been found that the stain added must form a very close union (chemical?) with the silver salts, the union must be at least such that the stain is not removed by washing. The fluorescent substance acts as a sensitizer and catalyzes the light reaction for the light-waves which it absorbs. A great many photochemical reactions have been brought about by the use of such catalyzing agents.

In 1900 a Russian, and later in the same year, Tappeiner and Rabb, found that if infusoria are placed in a 1 to 1,000,000 solution of acridin (a fluorescent substance) and the culture kept in the dark, the organisms are not injured, but if the culture is exposed to the diffused light of the laboratory, the organisms are killed.

The importance of these facts is evident. Living tissues and ferments may, by the presence of fluorescent substances, be sensitized so that they are destroyed by an exposure to visible light as though they were exposed to ultra violet light. In this connection it is interesting to note that physicists have, by improved methods of study, found that fluorescence is a much more common property of substances than was formerly believed, indeed, the search has turned so that now one looks for substances which do not fluoresce. And, moreover, fluorescence is particularly common in the organic compounds formed by living protoplasm. The two best known fluorescent substances are the characteristic coloring materials of the plant and animal kingdoms, chlorophyll and hemoglobin.

It appears as if the ability which plants have of forming carbohydrates from carbon dioxide and water is due to the photodynamic action of the fluorescent chlorophyll. We can form carbohydrates from water and carbon dioxide in the laboratory by the use of ultra violet light. In the plant in the presence of the fluorescent chlorophyll, the union is made by red and orange light.

It is interesting to note that under the conditions which, according to Arrhenius, must have existed before the carboniferous era, when the carbon of the coal and the rocks was in the atmosphere and when the earth thereby experienced a tropical climate nearly to the poles; under these conditions it has been shown that light waves shorter than red and orange could not have reached the surface of the earth. The plants, therefore, were forced to use a method whereby these rays could be utilized for photosynthesis. Hemoglobin, which is chemically so similar to chlorophyll and also fluoresces, has the complementary color of chlorophyll. It reflects the red and the orange—precisely those rays which the chlorophyll absorbs.

Hausmann found that the alcoholic extract of etiolated plants contains a fluorescent substance which has a photodynamic effect on the red blood corpuscles. Blood corpuscles were also sensitized by chlorophyll green and hematoporphyrin. He sensitized egg albumin to light by animal gall, bilirubin, urobilin and hematoporphyrin. He also sensitized red corpuscles by these substances. Later he injected hematoporphyrin into mice. Such injected mice if kept in the dark showed no signs of sickness, but if exposed to the diffused daylight of the laboratory they quickly developed reddening at the tip of the nose and tail, like sunburn, and soon died. Another investigator found that a frog's tongue sensitized with eosin and exposed for seven minutes to yellow light showed changes similar to those produced by ultra violet light.

Dryer and a number of other investigators have found that the eating of buckwheat produces a marked photosensitiveness in the skin of certain individuals, and he has succeeded in isolating a fluorescent substance from buckwheat flour.

The list of investigations given above leaves no room for doubt that physiological changes may result from photodynamic light reactions. Our bodies contain many substances which under proper conditions may act as sensitizers. For example, hemoglobin does not sensitize until it has escaped from the corpuscle. But there are many pathological conditions which are attended by hemolysis. Any increase in the photosensitiveness which may attend these conditions may have escaped our notice. Finsen's red light treatment for smallpox is interesting in this connection. Ryan, the present director of the Finsen Light Institute, claims to have had uniformly excellent results with the red light treatment for the last 22 years. Ryan emphasizes the rule which Finsen laid down in his early papers: In studying the effects of light upon organisms which have been sensitized by photodynamic substances, one must use the same care in excluding light from the controls as is used in the handling of photographic plates.

Since visible light has a much greater penetrating power than ultra violet light, the pathological conditions produced by photodynamic light reactions will probably be more deeply seated than those produced by ultra violet light. A large per cent. of "sunlight" ultra violet light is absorbed in the blood stream, in which tissue important photochemical changes take place. Visible light may have an effect on sensitized tissues as destructive as that of ultra violet light on normal tissues.

Fluorescence of Dyes.

Neuberg and *Galambos* (Biochem. Zeitsch., 1914, 61, 315; J. Chem. Soc. 1914, Abs. 106, ii, 402) have noted the action of dyes on glycerol, alanine, and tartaric acid. Dyes from the following groups were selected: Fluorescein, rhodamine, anthracene, acridine, triphenylmethane dyes, ethyl-red, nigrosine, and aesculine. Of the dyes investigated, sodium dichloroanthraecenedisulphonate, and sodium anthracene-2:7-disulphonate, were the only substances which were found capable of inducing decomposition of chemical substances in light, and they produced in this way degradation of a large number of organic substances. The theory of the action is discussed by Neuberg and Galambos, who reject von Tappeiner's idea that dyes act catalytically in light by virtue of their fluorescing properties. They suggest that the active substances can function as oxygen acceptors in light.

When a condenser spark passes between aluminum electrodes screened by a metal strip, although nothing is visible to the eye, a photograph taken with a quartz lens shows that the air around the spark is glowing with ultra violet light for a very short distance. This was shown by *Wood* (Phil. Mag. 1910, *20*, 707) not to be due to fluorescence of the air caused by the absorption of Schumann waves or to scattering of the light of the spark by air or dust. This phenomenon was further investigated by *Wood* and *Hemsalech* (Phil. Mag. 1914, *27*, 899), who used an improved form of apparatus. The fluorescence excited by the radiation from the spark was resolved by a quartz prism placed in front of a quartz fluorite achromatic lens, behind which was situated the plate on which photographs were taken. In this way, the spectra obtained in an atmosphere of oxygen, nitrogen, air, carbon dioxide, hydrogen, and coal gas have been examined. The most interesting results are those obtained by comparing the fluorescence of gases in a stationary and in a moving condition. Some gases show a much more brilliant fluorescence when moving across the jet of rays from the spark whilst the others show no luminosity in these circumstances, although they respond vigorously to the excitation when quite stagnant. *Steubing* (Physikal. Zeitsch. 1914, 15, 742-744) criticizes the view that ultra-Schumann waves are emitted by spark discharge and maintains that no satisfactory proof has yet been given: (1) that the fluorescence spectrum is different from that of the exciting spark discharge; (2) that shattering of the light emitted by the spark discharge is eliminated by the experimental arrangement adopted by Wood and Hemsalech; and (3) that ultra-Schumann waves are actually emitted by the spark.

Kennard, (Chem. Abs. 1918, 650; Cornell Univ. Phys. Rev. 1918, 38) considers fluorescence a reversible process. Assuming that fluorescence and thermal radiation are thermodynamically independent and that the energy of fluorescence is derived from that of the exciting light, it is shown that in the case of an isolated unitary band the relative intensity in the fluorescence spectrum is proportioned directly to the product of the exciting power and the intensity in the black body spectrum for the temperature of the substance, all being taken for the same wave length. Experimental data seems to confirm this relationship.

Effect of Specific Rays on Animal Tissues.

Moycho (Compt. rend. 1913, *156*, 577) exposed the external surface of the ear of a rabbit to short irradiation for (thirty seconds) without producing any visible effect. If this is prolonged for one to twelve minutes, however, a series of phenomena appears. After two to five hours, local vaso-dilatation is noticeable, the portion which was exposed to the rays becoming red, this being accompanied by rise in temperature and tumefaction. The maximum effect is reached in twenty four hours, then diminishes and finally at the end of seven to twelve days the redness and high temperature completely disappear, and a persistent brown pigment appears. The irradiation appears to have a stimulating effect on the hair growth. The most active rays are those having λ = 3100 — 2900, and the cells acted on are situated at a depth of 1/10th to 1/6th mm. below the surface. *Henri* and *Moycho* (Compt. rend. 1914, *158*, 1509; J. Chem. Soc. 1914, Abs., *106*, i, 902) studied the effect of monochromatic ultra violet rays, from λ2300 to 3300, on the ear of a rabbit, the time of exposure for production of a redness after twelve to twenty-four hours, being measured. The extreme ultra violet rays 2300-2500 have no sensible action on the tissues of the ear. The most active region in the ultra violet is at λ2800, the energy necessary to produce an irritation of the tissues being 0.057×10^7 ergs. For λ3300, no visible effects could be obtained. At the sea level the solar spectrum stops at about 3000, and the amount of energy which reaches the earth from this region of the spectrum is such as would produce sunstroke in one hundred minutes. At levels higher than this, the time of exposure would get less as the height increased. If, instead of continuous radiation, the ear is subjected to intermittent treatment, the visible effect is produced when the sum of the short radiations is equal to the continuous radiation, providing that the intervals between the application of the light do not exceed forty-eight hours. (Compt. rend. 1913, *156*, 1268.)

Burge and *Neill* (Amer. J. Physiol., 1915, 88, 401; J. Chem. Soc., 1915, Abs. 108, i, 1042) observe that fluorescent bacteria are relatively highly resistant to the destructive action of ultra violet rays. Like the lens protein, they are able to protect themselves from coagulative effect of these rays by being able to convert rays of short wave-length into longer waves, and thus dispose of the energy of the absorbed short waves. This power is absent in non-fluorescent bacteria.

Thiele and *Wolf*, (Arch. Hyd., 60, 29; Chem. Abs. 1907, 1029) in an investigation of the destruction of bacteria by light, state that ultra violet waves kill bacteria rapidly at 14°—20° and that the destructive action is hastened at higher temperatures. With visible waves the effects are less intensive. The bactericidal action is not due to the hydrogen peroxide which is formed by the light.

Agulhon (Compt. rend. 1911, 153, 979) concludes that enzymes are divisible into three classes according to their sensitiveness to light, Sucrase, tyrosinase, and laccase are destroyed by visible rays only in the presence of oxygen; in a vacuum they are destroyed only by ultra violet light. Probably in the absence of molecular oxygen, hydrogen peroxide is the effective agent of decomposition. Emulsion and catalase are destroyed by light of all wave-lengths, even in a vacuum, but more rapidly when oxygen is present. Rennet is an example of a third type, the activity of which is impaired by visible rays, but is rapidly destroyed by ultra violet radiation in a vacuum.

Amylase and Lipase.

Two methods have been employed by *Chauchard* (Comp. rend., 1913, *156*, 1858) in the study of the effect of variation in the wave-length of the ultra violet light employed on the rate of destruction of amylase. In the first of these, the source of light is the spark passing between cadmium electrodes. The light is filtered by suitable screens and allowed to traverse the solution of amylase, when it is found that the rays $\lambda=2469$, 2300 and 2195 are more active than those of greater wave length. In the second series the light from a spark passing between magnesium, cadmium, or zinc poles is resolved by two quartz prisms, and the individual rays are allowed to act on the amylase solution. The amount of decomposition is found to increase as the wave-length of the light employed decreases. By a comparison of these results with the absorption of the different rays by the amylase solution, the conclusions are reached that: (i) the photochemical action of ultra violet rays on a solution of amylase is proportional to the absorption of these rays by the solution, and (ii) an amount of radiant energy sufficient to raise the temperature of the solution through only ¼ degree is capable of bringing about the destruction of 40 per cent. of the amylase. Chauchard (Compt. rend., 1914, *158*, 1575) further reports that the amylase of pancreatic juice is attacked appreciably only by rays where $\lambda = 2800$. The action increases very rapidly as the wave-length diminishes. The lipase is destroyed by the rays, where $\lambda = 3300$, these being without action on amylase. No relationship exists between the absorption of ultra violet rays by pancreatic juice and the action on lipase or amylase, owing to the presence in the juice of different substances which absorb the ultra violet rays unequally.

Acids and Esters of Plants.

Attention is called by *Spoehr* (Biochem. Zeitsch. 1913, *57*, 95; J. Chem. Soc., 1914, Abs., *106*, ii. 120) to the fact that plants have a more acid reaction in the morning, and that the acidity, for the most part, disappears on exposure to light. It is shown that certain plant acids, especially diabasic acids, readily undergo decomposition (but only in the presence of air) when exposed to ultra violet light in quartz vessels. Malic and tartaric acids lose two molecules of carbon dioxide under these conditions, and the alcohols thus formed are oxidized further to acetaldehyde and acetic acid. The latter acid also undergoes decomposition, yielding formaldehyde and formic acid. The last named acid yields carbon dioxide as final oxidation product. Acetaldehyde, under these conditions of light-oxidation, can give rise to oxalic acid. Under the conditions of light-oxidation, therefore, the ordinary plant acids can give rise to volatile oxidation products. The discovery of formaldehyde as a product of light oxidation of acids throws some doubt on the significance of Baeyer's hypothesis, according to which the aldehyde is a direct photochemical product of carbon dioxide, as it can be produced from plant acids. Stoermer and Ladewig (Ber. 1914, *47*, 1804) suggest that ester formation in plants is due to the ultra violet rays of sunlight.

Test Paper Sensitive Only to Ultra Violet.

Schall (Chem. Ztg., *34*, *267*) notes that paper prepared with p-phenylenediamine nitrate (2/3 normal) is sensitive only to waves shorter than 313 *μμ*. As the solar spectrum ends at about 295, the paper is suitable for determining the variations (e.g., with altitude) of the solar radiation of short wave length and has been used for this purpose.

Heraeus Lamp for Chemical Tests.

A mercury vapor lamp of the Heraeus type used by *Foster* (J. Chem. Soc. Trans., 1906, *89*, 913) is shown in *Figure* 1. The essential part is a small bore tube A, of quartz, bent into U-shape with the arms close together. The uper ends are bent over and end in bulbs, which are filled with pure mercury up to the level shown. Platinum contact wires pass down two other tubes which are sealed into the bulbs at the back. The bulbs, inlet tubes for the wires, and part of the U-tube are all inclosed in a brass casing C, which has a glass front not shown in the sketch. The projecting part of the U-tube is inclosed in a thin-walled quartz tube, B, which is cemented into the brass casing. Close behind the U-tube a nickel tube enters, through which water flows. The water fills the whole of B and C and is carried away by another tube at the top, so that a water-jacket surrounds the lamp and keeps it quite cool. The lamp is lighted by inverting it slowly so that the two threads of mercury in the U-tube meet at the bend. On turning the lamp in the reverse direction, the arc is struck, and fills the whole of the U-tube up to the mercury bulbs. A starting resistance is necessary owing to the momentary short circuit which occurs when the mercury threads meet. The lamp requires

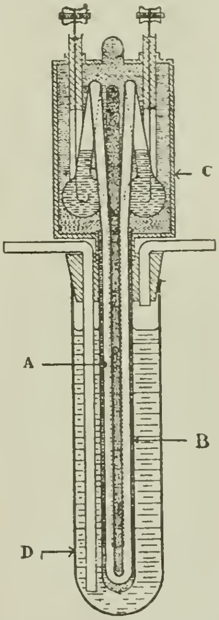

Figure 1.

230-240 volts, and uses 5-6 amperes. The solutions undergoing exposure were contained in a large tube. D, similar to a large test-tube, which was fitted to B by means of an india rubber stopper. Two glass tubes passing through this allowed gases to be bubbled through the solutions.

The lamp gives a very large amount of ultra violet radiation; when burning in air, a very powerful odor of ozone is perceived, and the radiation can be distinctly felt on the hand. If a N/1000 solution of potassium permanganate containing 9 per cent. of sulphuric acid is exposed to this light in the tube D, it is completely decolorized in ten minutes with evolution of oxygen. A solution of potassium iodide (0.09N) and starch becomes absolutely black in two minutes.

Uviol Lamp With Light Filter.

An apparatus used by *Luther* and *Forbes* (J. Am. Chem. Soc., 1909, 770) employing a light filter is shown in *Figure 2*. Three cylindrical glass tubes A, B, and C, were set in a ring-shaped pan of sheet tin, P; their lower edges were made concentric by suitable pieces of brass soldered to the floor of the pan, their upper edges by bits of wood. The average distance between A and B was 0.71 cm., between B and C 1.56 cm. Two small glass tubes, not shown in the cut, were passed through holes in the pan, barely projecting into the spaces between A and B, and B and C, respectively; through these tubes a solution in either compartment could be drawn off at pleasure. The inner edge of the pan could be kept cool by a current of water flowing through D, a coil of small lead tubing. Next, the pan was filled with melted cement, which, on cooling, made the apparatus tight. The source of light was a uviol mercury vapor lamp U clamped in the axis of the apparatus. The mixture to be exposed to light was placed in the outer vessel or compartment. The latter was cooled by a glass tube wound in a double spiral, through which flowed brine at a temperature below zero from a large reservoir placed above the apparatus and filled with water, ice, and salt; the brine was forced back into the reservoir by a small mechanical pump driven by an electric motor. The spiral was made to act as a stirrer at the same time by hanging it to an eccentric E on a wheel high above the apparatus and rotated by the motor. To prevent the moisture which collected on the cold shafts of the spiral from flowing down and diluting the solution, a small cup of lead foil was cemented about each shaft; these cups never touched the reaction mixture. The light filter solution was placed in the inner vessel or compartment. The latter was cooled and stirred by a different device: a Liebig condenser with cold water jacket was suspended above the apparatus; a filter pump was connected through a capillary and a large bottle to the upper end of the condenser tube; from the lower end a finer tube ran down below the surface of the filter solution. When the pump was started, the liquid was drawn up into the condenser and cooled, but as soon as the liquid fell below the end of the tube, air rushed up through the condenser and restored normal pressure throughout the system; thereupon the liquid ran back into the light filter vessel before a partial vacuum could again be established through the capillary. This operation repeated itself at regular intervals.

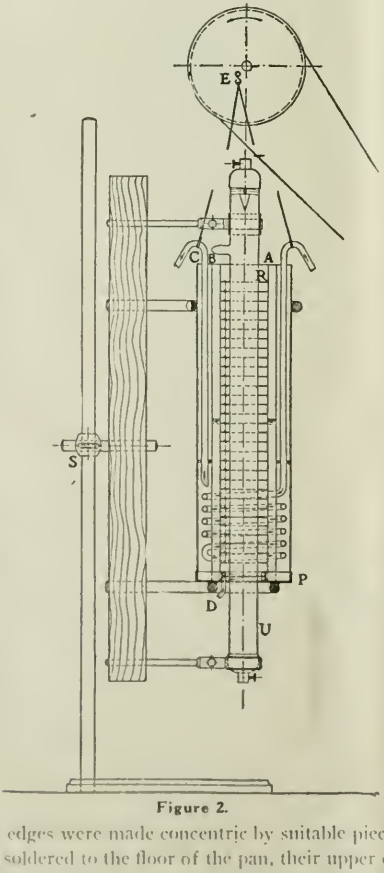

Figure 2.

The Distribution of Energy in the Radiation from the Uviol-Glass Lamp.

Allmand (Trans. Chem. Soc. 1915, 107, 682; J. Chem. Soc., 1915, Abs., 108, ii, 400) has determined the distribution of energy in the radiation emitted by a Schott mercury Uviol-glass lamp by direct measurement of the intensity of the different bands by means of a thermopile. The light was resolved by means of a Hilger monochromatic illuminator, and the thermopile current measured with the aid of a Paschen galvanometer. The intensities of the bands, referred to the blue band = 1, are compared with the corresponding values (in brackets) obtained by Winther, who used a fluorometer for the energy measurements. The numbers obtained are: λ 571 $\mu\mu$, 0.27, (—); λ 541, 0.73, (—); λ 436, 1.00, (1.00); λ 405, 0.56, (0.29); λ 362, 0.42, (0.25); λ 313, 0.17, (0.045). On comparison of the results with those obtained for the quartz lamp by Ladenburg (Physikal. Zeitsch., 1904, 5, 525), it is found that the relative intensities of the blue (λ 436) and violet (λ 405) bands are approximately the same for the two lamps, but that the intensities of the ultra violet and of the green and yellow bands relative to the blue are much smaller for the Uviol than for the quartz lamp.

By applying the results to the data obtained by Luther and Forbes (J. Chem. Soc., 1909, Abs., 96, ii, 632) in the investigation of the photochemical oxidation of quinine by chromic acid, it is found that the ratio of the intensities of the bands λ 406 and λ 362 is 1.00:0.75, which is in good agreement with the corresponding ratio of the velocity-coefficients, 1.00:0.82. This would seem to show that the reaction velocity is proportional to the absorbed energy, and independent of the frequency of the light.

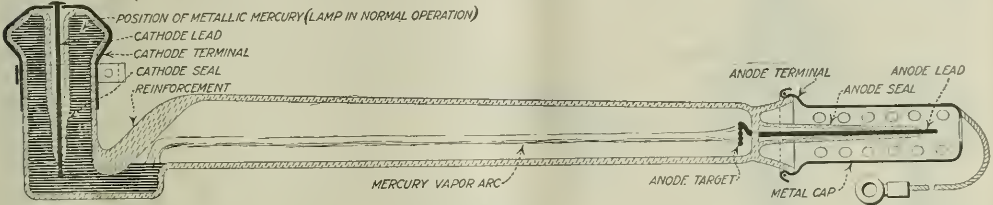

Figure 3.

Aluminum Arc.

In some investigations conducted by *Ross* (J. Am. Chem. Soc., 1906, 786) on the chemical action of ultra violet light, the source of light was obtained by causing an oscillatory spark to pass between aluminium terminals joined in the secondary circuit of a large induction coil used as a transformer. In the secondary circuit was also joined in parallel a large Leyden jar. Through the primary circuit was passed an alternating current of 110 volts having a strength of 3.4 amperes. To obtain a constant source of light proved a matter of considerable difficulty. However by arranging an apparatus as thus described and having in the primary circuit an ammeter and resistance boxes, the resistance could be changed at will and the strength of the current thus kept constant. When a uniform current was in this way maintained, the amount of energy given out by the spark during intervals of ten minutes was practically constant. This was shown to be the case by the fact that the same amount of iodine was set free from equal volumes of potassium iodide solution, when exposed to the light under exactly the same conditions for equal intervals of time. After every observation the aluminium terminals were sharpened, and then placed the same distance apart so that every exposure might be begun under the same conditions. The terminals used were large—3 mm. by 8 mm. cross-section—and were allowed to rest for the greater part of their length on iron plates placed 7 cm. apart. In this way the heat generated by the spark was rapidly conducted away. By placing the proper amount of ice in small dishes resting on the terminals, the temperature of a solution of 3 cc., placed in a cell directly underneath the spark, could be kept within a range of 1° during an exposure of ten minutes. Aluminum terminals were used on acount of the strong ultra violet rays given out by a spark passing between them. The rate of decomposition produced by the light in the case of the iodides, when terminals of aluminum were used, was found to be at least twice as great as that resulting when terminals of any of the other common metals were used. Cadmium could not be used on account of its softness. An accurate comparison of the decompositions produced, when electrodes of different metals were used, was not made, since, on account of their difference in hardness, the experiments could not be carried out under comparable conditions.

Ultra Violet Tungsten Arc.

According to *Luckiesh* (J. Frank. Inst., 1918, 552) there is not available a light source emitting a continuous spectrum between 200 and 400 $\mu\mu$. The quartz mercury arc emits many lines in this region, but the spectrum does not approximate continuity. Some arcs (particularly flame arcs) and electric sparks provide ultra violet spectra which find many uses, but these are not usually steady sources. The ultra violet spectrum of a tungsten arc is very rich in lines in this region, and inasmuch as a tungsten arc can be made to operate quite steadily in certain gases, its spectrum was studied with the aim of determining the adaptability of such an arc to various problems. A glass bulb was provided with a quartz window opposite the tungsten electrodes. Commercial argon, containing about 20 per cent. of nitrogen, was admitted to the evacuated bulb at a pressure of 20 cm. of mercury. Spectrograms were made for currents varying from 0.3 ampere to 5.0 ampere. For this particular arc the ultra violet energy between 200 and 300 $\mu\mu$ is relatively weak for the lowest currents at which the arc operates. Spectrograms are shown for currents up to one ampere, the exposure being constant for the entire group. The spectrum between 300 and 400 $\mu\mu$ may be considered approximately continuous for some purposes, although shorter exposures show that it is somewhat fluted in character. The arc voltage varied from 28 to 16 volts as the current increased from 0.3 to 5.0 amperes respectively, thus consuming from 5 to 80 watts. This arc was quite steady and is adaptable to many physical and chemical problems. It may be made much more powerful to suit requirements.

Hot Anode Lamp.

A quartz mercury vapor lamp known as the "hot anode" type is manufactured by the R. U. V. Company, New York City, N. Y. (Met. & Chem. Eng. 1918, 43) which is novel, in that there is no mercury chamber at the anode end. This is shown in *Figure* 3. In place of mercury, a tungsten target composed of a spiral formed of tungsten wire is used. The anode end is protected from mechanical injury by means of a metal cap which also serves to lead the current to the anode. The cathode end is reinforced with thick quartz to absorb the shock of the mercury vapor and is set at an angle which is claimed to reflect back into the luminous portion of the tube some ultra violet rays which would otherwise escape. The cathode end is also protected by a metal cap through which the current is led to the mercury. The tungsten wire which serves to lead the current into the lamp is sealed into the quartz tube by a graduated mixture of quartz and glass so that at the end there is practically pure glass, while the portion next to the quartz tube is practically pure quartz. It is claimed that this combination of glass and quartz provides a proper co-efficient of expansion so that the loss of vacuum is prevented. Having only one mercury electrode, this lamp is capable of being operated either in a vertical or horizontal position, which in certain cases is of advantage.

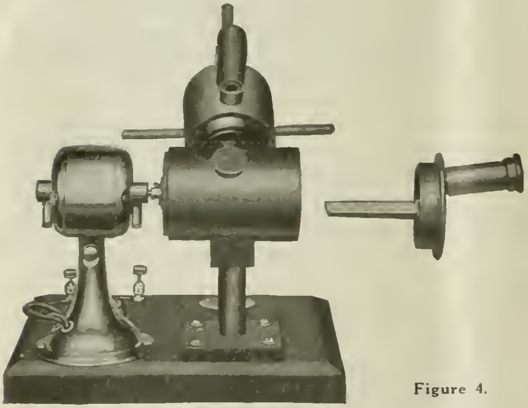

Figure 4.

The Phosphoroscope.

A form of phosphoroscope is described by Andrews (General Electric Review, 1917, 259) which consists of a source of ultra violet rays, a chamber containing a tray upon which the substance under examination is placed, a light proof chamber for holding the tray and a small motor which operates a revolving shutter. (See *Figure* 4). Eye pieces are placed in the light-proof chamber for observing the effect of the light upon the substance under examination. As the boundary between fluorescence and phosphorescence is not sharply defined it is very difficult to determine whether a given substance continues to glow after being exposed to invisible light rays as a small fraction of a second may be the life of the phosphorescence, although in other cases the material may continue to glow for several hours after being exposed. In operating the apparatus the substance to be examined is placed on the tray and the motor started, thereby revolving the shutter at a speed which cuts off the light at from 3000 to 4000 times per minute. In case the substance shows continuous illumination it is phosphorescent, while if the substance appears to flicker it is fluorescent. A general idea of the range of time which a given substance continues to phosphorize may be obtained by changing the speed of the motor thus lengthening or shortening the period of illumination and the period of darkness.

An arrangement of apparatus is described by *Hauer* and *Kowalski* (Physikal. Zeitsch., 1914, 15, 322; J. Chem. Soc. 1914, Abs. 106, ii, 320) which has been found suitable for the examination of the phenomena of luminescence. It consists of a monochromatic ultra violet illuminator and a spectrophotometer adapted to the measurement of the intensity of comparatively faint luminescent radiation. Various observations made with this apparatus are described. It is shown that the momentary and progressive phosphorescence of phenanthrene can be readily distinguished, and that the progressive bands are only excited by light which falls within the region of selective absorption of the phenanthrene. From experiments with lithium platinocyanide it is found that the intensity of the fluorescent light reaches a maximum when the wave-length of the exciting light is $\lambda = 390\ \mu\mu$. The data obtained with rubidium platinocyanide seems to show the existence of a maximum fluorescence, the position of which depends on the wave-length of the excitation. From observations on the phosphorescence of calcium sulphide containing samarium as "active impurity" at different temperatures, it has been found that the rate of decay of the phosphorescence increases with the temperature, but this temperature effect varies from one band to another, and thus gives rise to change in color of the phosphorescent light during the process of decay. For different bands the phosphorescent attains a maximum at about the same temperature, but since the influence of temperature on the intensity varies from one band to another, change of temperature produces a change in the color of the phosphorescent light.

Separating Visible from Invisible Light.

Andrews (General Electric Review, 1917, 817) furnishes details of an apparatus for separating visible from invisible light, the theory of the apparatus being that the visible light is less refracted by a lens than is ultra violet light. *Figure* 5 diagrammatically shows the design of the apparatus. A is a source of visible light, also producing ultra violet rays, such as may be produced by a high tension disruptive spark between iron terminals. B is a quartz lens. D is a thin sheet of metal pierced with a pin-hole at C, the diaphragm being so placed that the pin-hole is in the exact mean focus of the ultra violet rays. E indicates the mean focus of the visible rays. F is a small metal disk and G is a screen. A front view of the screen is shown at H. The operation of this instrument is based on the fact that the mean focus of visible light is located at a measurable distance beyond the mean focus of invisible ultra violet light owing to the greater refrangibility of the latter over that of the former. If, therefore, the diaphragm D is carefully adjusted so as to bring the pin-hole C into the exact mean focus of ultra violet light, the rays of the latter will pass through the pinhole and spread out again on the other side of the diaphragm. The mean focus of visible light being some distance beyond the pin-hole, its rays will be largely intercepted by the diaphragm, and through the pin-hole only a few of the nearly parallel rays of visible light will pass. In operation, if the screen H is made of non-fluorescent material, there will appear on it only the small illuminated spot K, but if it is coated with a fluorescent substance, such as powdered willemite, this small luminous spot will be surrounded by a disk of bright green light produced by the fluorescence of the willemite excited by the circular field of invisible ultra violet rays. Should it be found desirable to cut out the spot of visible light, the small metal disk F can be set up in such a position as to cast its shadow over the spot K and so transform it from a bright spot to a dark one, leaving the disk of green fluorescent light otherwise unchanged.

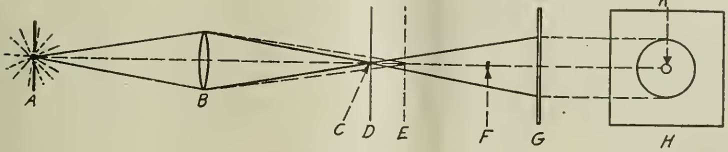

Figure 5.

This apparatus is valuable for the determination of the exact fluorescent colors of various compounds. When such compounds are exposed to the direct rays of an open iron spark, their true fluorescent color is masked to a greater or lesser degree by the visible light component of the spark, this being especially the case with compounds that show only a weak fluorescence. When a compound is placed within the invisible field of the ultra violet rays of this separator, it shows its true fluorescent color and the fluorescence, if pronounced, manifests itself on a visually dark field, as an illumination of a surprising character.

An apparatus for subjecting air to light rays and producing ozone is described by Markel (Chem. Abs., 1918, 644) Can. Pat. 182,371, Feb. 19, 1918). Nonconducting plates having the corresponding faces covered with powdered iron are so arranged in a receptacle that the air can pass around the edges. The coatings are claimed to prevent arcing except through the nonconducting plates.

Electric Accumulator.

Winther (Zeitsch. Elektrochem. 1912, *18*, 138; J. Chem. Soc., 1912, Abs., *102*, ii, 318) suggests a novel form of electric battery based on the reaction between ferrous and mercuric chlorides. When an aqueous solution of ferrous and mercuric chloride is exposed to ultra violet light, the system is partly transformed into ferric chloride and calomel. The reverse reaction proceeds spontaneously and completely; it is extremely slow at the ordinary temperature, so that the products can remain in contact without appreciable change, but when arranged to give a current, it goes at a much greater rate, which depends on the temperature. For purposes of investigation the cell was constructed as follows: In a glass funnel, closed at the lower end, a perforated platinum plate was fixed; the plate was soldered to a platinum wire which passed out through a hole in the funnel. On the plate a layer of platinized asbestos was placed and then the solution which was exposed to the light from a quartz-mercury vapor lamp. After the illumination the differences of potential were measured, a platinum electrode being placed for this purpose in the upper liquid. The E.M.F. in some cases was as much as 0.1 volt, and currents of 1 milliamp. were obtained. The results were complicated by the oxidation of the ferrous salt by the oxygen of the air; the effect of this process on the equilibrium is discussed in detail. Another uncertainty arose from the fact that owing to insufficient stirring the concentration of ferric chloride was not the same in the upper and lower layers. The apparatus was also exposed to sunlight and gave E.M.F.'s of 20-30 millivolts, but owing to the slowness of the action the results were greatly complicated by direct oxidation.

Light and Electric Energy.

Reactions which can be induced photochemically and electrochemically have been compared by *Smiths* and *Aten* (Z. Elektrochem. *16*, 264; Chem. Abs. 1910, 1842). Ultra violet rays (from a mercury lamp) transmitted through quartz and the discharge from an ozonizer were used to produce the photochemical and electrochemical equilibria respectively. It seems probable that the action of light and of the electrical discharge is the same, namely, a displacement of the equilibrium in the endothermal direction. An attempt to produce the decomposition, $I_2 = 2I$ (as judged by the change in pressure) was unsuccessful, as was also the attempt to obtain compounds from chlorine and oxygen and from nitrogen and iodine.

Thompson (Proc. Camb. Phil. Soc. 14, 417, 1907) exposed various gases to the action of ultra violet light and observed the effect of this exposed gas on an electroscope. When exposed to ultra violet light, air increased the natural leak eight times, carbon dioxide sixteen times and ammonia over one hundred and fifty times. The light rays which produce this ionization are absorbed by a few millimeters of air.

Improvements in the Manufacture of Synthetic Phenol

According to the well known process, phenol is prepared from benzene, by successively sulfonating the benzene in presence of an excess of sulfuric acid, and decomposing the sulfonate by means of sodium hydroxide, in excess. At the completion of this stage of the reaction, the phenol exists as sodium phenolate and is liberated by neutralizing the phenolate by any appropriate acid.

The decomposition of the sodium phenolate was formerly accomplished by mineral acids, such as hydrochloric or sulfuric acid, and later by carbon dioxide. The use of carbon dioxide has the advantage that the sodium is recovered in the form of carbonate, and can either be used as such or readily causticized.

In the decomposition of the phenolate by carbon dioxide, it has been found that in case the pure (undiluted) gas is used, the reaction is rather sluggish, although it is eventually completed with good yields of phenol. The undiluted gas is, howeve, relatively expensive. If, on the other hand, lime-kiln gases are employed in lieu of pure carbon dioxide, the reaction proceeds much more slowly, and there are material losses of phenol, which is swept away by the nitrogen with which the lime-kiln gas is diluted.

Henry Howard of Boston (Amer. Pat. 1,245,343, of No. 6, 1917) has devised a method to overcome these difficulties.

According to his invention, the sodium phenolate prepared as usual by the caustic fusion of the sulfonic body, is decomposed by sodium bicarbonate, preferably employed in the proportions required to transform all of the sodium present into normal sodium carbonate.

Under these conditions the reaction is very rapid and even practically instantaneous. The reaction proceeds at normal and higher temperature, and is exothermic. 60° C. is a satisfactory operating temperature, although either higher or lower temperatures may be used. A concentration of the phenolate solution in the neighborhood of 23° Baumé is satisfactory in practice. To avoid unnecessary dilution the bicarbonate may be added in the solid form, although this is not essential. Most of the phenol rises to the surface of the liquid and may be separated by decantation, the remainder being recovered from the carbonate solution in any appropriate way, as for instance by distillation, or by blowing steam through the liquid.

About one-half or somewhat less of the sodium carbonate solution produced as above is treated in any suitable apparatus with lime-kiln gas, and is thereby reconverted into sodium bicarbonate, which is used for the treatment of another batch of sodium phenolate. The remainder of the sodium carbonate solution is causticized by lime, and may be concentrated for re-use in the preparation of the phenolate.

The method is, naturally, applicable to the preparation of phenols in general.

Another process for accomplishing the same purpose has been perfected by Herbert S. Kimball, of Newton, Mass. (Amer. Pat. 1,245,353, of Nov. 6, 1917), and is assigned to the Merrimac Chemical Company.

His invention is carried out as follows: Benzene is first sulfonated and the resulting sulfonic acid, containing an excess of sulfuric acid, is wholly or partly neutralized by calcium sulfite, utilizing for this purpose the calcium sulfite produced at a later stage of the cyclical process, as explained below. The neutralization is effected in closed tanks, and the evolved sulfur dioxid, or such portion thereof as may be required, is employed to decompose the sodium phenolate as described below. In case the quantity of calcium sulfite available is insufficient for complete neutralization of the sulfonic acid, it is supplemented by lime or limestone.

The calcium benzene sulfonate, obtained as above, is treated with the molecular equivalent of sodium sulfite, and is thereby transformed into sodium benzene sulfonate. The sodium sulfite may be introduced either in solution or in solid form. The calcium sulfite, which separates out, is applied toward the neutralization of the sulfonic acid produced in the first step of the process.

The sodium benzene sulfonate is now subjected to a caustic fusion to produce sodium phenolate, which in turn is decomposed by sulfur dioxide (undiluted) arising from the neutralization step of the process. The phenol is decanted, and the remaining liquor, containing sodium sulfite or bisulfite or a mixture of these, is utilized in part for the conversion of the calcium benzene sulfonate into the corresponding sodium salt as above described, and is in part causticized by lime, yielding a dilute caustic soda solution, and calcium sulfite, the latter available for neutralizing the benzene sulfonic acid. If desired the caustic soda solution may be concentrated and returned to the cycle.

A complete cycle embodying the invention is shown on the accompanying diagram.

The use of sulfur dioxide for decomposing sodium phenolate, forming one phase of this cycle, is the invention of Mr. H. Howard, who has applied for a patent on the same.

Exports of Indigo from Madras

U. S. Consul Lucien Memminger writes from Madras, India, to Commerce Reports, that exports of indigo from the Madras Presidency to foreign countries during the seven months from April 1 to October 31, 1917, according to figures furnished by the Custom House, were: To United States, 5,488 pounds, valued at $8,435; United Kingdom, 65,408 pounds, value $77,326; Straits Settlements, 21,056 pounds, value $19,093; Australia, 1,120 pounds, value $1,110; China, 8,736 pounds, value $11,320; Japan, 23,520 pounds, value $25,273; Ceylon, 28 pounds, value $9; total, 125,356 pounds, valued at $142,566.

INORGANIC CHEMICAL SYNONYMS

A Novel Work of Reference for Student and Chemist

By

ELTON R. DARLING*

Although Intended Primarily for the Student, It Is Believed that the Following Compilation of the Various Terms Employed to Designate Inorganic Chemicals Used in the Industries Will Prove a Convenience to the Experienced Chemist. The Writer Claims No Originality for the Synonyms, but Only the Bibliographical Research of the Material at Hand.

Part V Will Appear in the Next Issue.

PART IV

Lead, 207.1 (Plumbum).

Lead melts at 327° C. and boils at 1525° C. It has a valency of two and four.

This metal was known to the ancients. It was supposed to have been one of the seven metals known to the ancients and to have been connected with the seven heavenly bodies. Thus lead was apportioned to Saturn.

- Lead Acetate, 379.20.
  - *Plumbi Acetas*
  - *Plumbic Acetate*
  - *Sugar of Lead*
  - *Goulard Powder*
- Lead Carbonate, 267.10
  - *Plumbi Carbonas*
  - *Plumbic Carbonate*
  - *Flake Lead*
  - *White Lead*
  - *Ceruse*
  - *Lead Spar*
  - *Cerussite (native)*
- Lead Chromate, 323.10
  - *Plumbi Chromas*
  - *Plumbic Chromate*
  - *Chrome Yellow*
  - *Paris Yellow*
  - *Leipzic Yellow*
  - *Crocosite (native)*
- Lead Chloride, 277.02
  - *Plumbi Chloridum*
  - *Plumbic Chloride*
  - *Muriate of Lead*
  - *Horn Lead (native)*
- Lead Oxide, 223.10
  - *Plumbi Oxidum*
  - *Plumbic Oxide*
  - *Lead Monoxide*
  - *Lead Protoxide*
  - *Massicot*
  - *Brown Lead Oxide*
  - *Litharge (native)*
- Lead Dioxide, 239.10
  - *Plumbi Dioxidum*
  - *Plumbic Peroxide*
  - *Binoxide of Lead*
  - *Lead Peroxide*
  - *Black Lead*
  - *Puce*
- Lead Sulfate, 303.17
  - *Plumbi Sulfas*
  - *Plumbic Sulfate*
  - *Vitriolate of Lead*
  - *Anglisite (native)*

Magnesium, 24.32.

This metal has a specific gravity of 1.74, melts at 650° C. and boils at 1120° C. It has a valence of two.

Although magnesium was obtained as a metal in 1808, our knowledge of its history goes back to 1695. At that time a London physician published an account of a new salt found in the springs at Epsom. Shortly after this publication the medical value of the salt became known, being termed epsom salts. By 1700 several springs in England were found to contain it. Soon another medical salt, Magnesia Alba, was discovered by a Roman. Several methods were soon put forward for its preparation. In 1755 Black made an attempt to study the composition of these salts. Bergman made a more complete study in the same year, but it was Davy who, in 1808, proved that this compound was the oxide of a new metal and called it "magnium," which name soon gave place to "magnesium."

- *Kieserite (native)*

Manganese, 54.93.

It has a specific gravity of 7.42 and its melting point is 1225° C. It boils at 1900° C. and its valency is two, three and four.

The black oxide of Manganese has been known from the earliest times and was associated with magnetic iron ore. In fact, many of the alchemists believed it to be an ore of iron. Much mention was given to it in literature on glass making and long Latin manuscripts are found setting forth its uses.

In 1740 the first study of the oxide was made. At that time Pott proved that the product was free from iron. The year 1774 saw the renowned investigation of Scheele, who made such an exhaustive study of mineral manganese and its action towards oxygen. Using Scheele's experiments as a basis Bergman came to the conclusion that it was the calx of a new metal. Gahn was, however, the first to isolate this metal.

Mercury, 200.6 (Hydrargyrum).

It has a specific gravity of 13.6. The melting point is 38.85° below zero; its boiling point is 357.33° C. The atomicity is two in the mercuric compounds and pseudo-monatomic in the mercurous.

Although mercury is one of the oldest of metals, no mention of it is to be found in old Greek writings. Theophrastus called it "liquid silver" and Dioscorides called it "silver water"; both gave a method for preparing it from cinnabar. Pliny was the first to give it the name of Hydrargyrum, and used the name only for the pure metal

The first mention of the properties of mercury was made in 1610 by Isidorus.

The first dispute as to which class mercury belonged in was raised by Agricola and Libavius. The former classed it with the metals and the latter with the semi-metals. It was not until 1759 when Braune, of St. Petersburg, succeeded in freezing it, that the question was settled.

Civilian Workers Wanted for Ordnance Department

Men having a high school education, some shop training and the natural ability to adapt themselves to new work, may qualify for a Government appointment in which under Government instructors, they will receive the necessary training for the positions described below. Those who have the required technical training will be placed and advanced as quickly as their ability justifies.

Which One of These Jobs Suits You?

Inspectors and assistant inspectors, field artillery ammunition steel.

Inspectors artillery ammunition, cartridge cases, assembling, loading, forging, primers, detonators, shell and shrapnel machining.

Ballistic inspectors.

Metallurgical chemists and assistants.

Inspectors, powder and explosives.

Inspectors, cannon, forging operations.

Inspectors, gun carriages and parts.

Inspectors, gun fire control instruments.

Assistant inspectors, motor vehicles and artillery wheels.

Engineers and assistant engineers, for tests of ordnance materials.

Inspectors ammunition packing boxes.

Machinists, accustomed to work to 1000's of inch.

Send in your own application and urge your associates who may be qualified to do so. These positions are under civil service regulations, but applicants will not be required to report for examination at any place. Applicant will be rated in accordance with education and general experience. No applications will be accepted from persons already in the Government service unless accompanied by the written assent of the head of the concern by which the applicant is employed. Papers will be rated promptly and certification made with least possible delay. Apply or write for further information to C. V. Meserole, Special Representative of the Ordnance Department, U. S. A., Room 800, 79 Wall Street, New York City.

NEW PUBLICATIONS

"Polarimetry"

This Bureau of Standards circular presents a concise account of the basic principles of modern polarimetry. The rapid growth in the applications of polarimetry in the arts and sciences has caused an increased demand on the Bureau for testing and research. The new edition of this circular contains ten new tables, including the new Bureau of Standards Baume scale for liquids heavier than water. Results of recent researches are also given. There is added a considera tion of the polarization of low grade products, a resume of the work of the international commission for uniform methods of sugar analysis and amendments to the United States Treasury Department sugar relations.

This paper is now ready for distribution, and those interested may obtain a copy by addressing a request to the Bureau.

New Publications of the U. S. Bureau of Mines

(List 57.—April, 1918.)

BULLETINS.

Bulletin 137. The use of permissible explosives in the coal mines of Illinois, by J. R. Fleming and J. W. Koster. 1917. 110 pp., 8 pls., 17 figs.

Bulletin 148. Methods of increasing the recovery of oil from sands, by J. O. Lewis. 1917. 128 pp., 4 pls., 32 figs.

Bulletin 159. Abstracts of current decisions on mines and mining, by J. W. Thompson. 1917. 111 pp.

TECHNICAL PAPERS.

Technical paper 141. Laboratory determination of the inflammability of coal dust and air mixtures, by J. K. Clement and C. N. Lawrence. 1917. 35 pp., 1 pl., 15 figs.

Technical paper 155. Gypsum products, their manufacture and uses, by R. W. Stone. 1917. 67 pp., 9 pls., 10 figs.

Technical paper 162. Initial priming substances for high explosives, by G. B. Taylor and W. C. Cope. 1917. 32 pp.

Technical paper 181. Determination of unsaturated hydrocarbons in gasoline, by E. W. Dean and H. H. Hill. 1917. 25 pp.

Note.—Only a limited supply of these publications is available for free distribution, and applicants are asked to co-operate in insuring an equitable distribution by selecting publications that are of especial interest. Requests for all papers cannot be granted. Publications should be ordered by number and title. Applications should be addressed to the Director of the Bureau of Mines, Washington, D. C.

The Amylo Saccharification Process

(*Concluded from page* 207.)

found very efficient) and the filtered solution again concentrated to incipient crystallization or left in a syrupy consistency. A corn cob extract is preferably added when put up for table use. The product thus obtained has a very fine flavor, due principally to the fact that when saccharification is quite rapid, a great deal of the sugar is present as maltose.

Washington, D. C., Feb. 2, 1918.

The Physical Basis of Color

(*Concluded from page* 218.)

acting transmitted waves is small, and the molecule is therefore not set in such strong vibration, although in many cases (fugitive colors) even this is sufficient to produce decomposition. On the other hand, a dyestuff fast to light must possess a stable molecule capable of absorbing light waves of large amplitude and of being set in strong vibration thereby without destructive action. Large molecules of simple symmetrical structure, without reactive side chains and substituents, particularly fulfil these requirements. In such a case the increase in size of the molecule through chemical action with the fibre produces favorable results, as is the case in wool dyeing. The physical nature of cotton dyeing precludes such a stabilizing action, and other methods are necessary. For example, the stabilizing action of combination with metallic oxides or of after-treatment of dyed material with copper salts."

Sulfite Pulp Waste as Raw Material for Dyestuff Production

Much study has been devoted to the problem of utilizing the vast amounts of waste sulfite lye resultant from the manufacture of wood pulp for use in paper making. The quantity of these waste liquors is such that they constitute a growing source of pollution for streams and rivers. It is estimated that the annual waste from American pulp works exceeds three billion gallons.

Of recent years not a few attempts have been made to employ the material in the production of dyes, and several patents have been granted to processes having this end in view. Pulp waste contains considerable amounts of a complex organic substance termed variously lignone, lignior and lignose. This substance is susceptible of being changed into coloring matters by two different methods.

The first is based upon fusion with sulfur and sodium sulfide. The resultant black and brown dyes are quite fast. They are probably closely allied to Cachoude Laval, also produced from the action of sulfur and sulfides upon a variety of forms of organic refuse, mainly containing cellulose.

The second method involves the nitration of the material either alone or after combination with various aromatic amines. The colors obtained range from light yellow to dark brown, and they are exceedingly fast after treatment with copper or chromium salts.

While there seems to be no question of the value of the dyestuffs and their availability for diversified use, the cost of production may prove to be a serious obstacle to any general use. The dilution of the waste lyes is often such that the expense attendant upon evaporation might alone exceed the cost of competing colors now on the market. In some pulp works, the amount of water is restricted, the lyes are more concentrated and waste steam is available for evaporation. Under such conditions it is quite possible that the dyes from lignone may be produced at favorable rates and may afford a welcome addition to coloring materials of purely domestic origin.

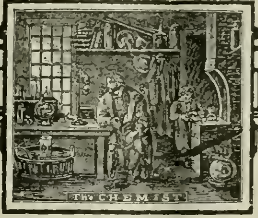
In this connection the statement is made that a paper-mill chemist in Finland claims he is able economically to produce methyl alcohol, cymol, and furfurol from sulfite lyes. He has taken out patents in Scandinavia, Russia, and Switzerland, and this has been followed by the starting of a color factory in Tammersfors, the centre of the Finnish textile industry. Here in the Technical Club, Dr. Wiljanen read a paper explaining this novel invention, and exhibited about ten different colors produced from cymol, and numerous others containing cymol as a substantial part. The lecturer claimed that about 300,000 kilos of cymol are obtainable annually in Scandinavia as a by-product. From this material yellow and red cotton and wool colors were producible in a simple manner, and other colors by more complicated methods. Finland's largest paper-mill association, Kymmene Aktiebolag, has installed apparatus in its sulfite factories for separating wood spirit, cymol, and furfurol, and research chemists in the new factory in Tammersfors are continuing the investigation. They are preparing to start in the near future the manufacturing of cymol colors.

Million Dollar Potash Corporation.

The Atlantic Potash Corporation has been incorporated at Dover, Del., with a capital of $1,000,000 to manufacture potash and chemicals.

CHEMICAL INVESTIGATION
EFFICIENCY & CONTROL

CONDUCTED BY CHARLES B. DAVIS, F.C.S.



ALL classes of work covered by the following subjects will be done for readers of "The Chemical Engineer" through this department by Mr. Davis: Special research of every description; analysis and reproduction of any commercial product; prevention of waste and utilization of by-products on the most economical basis; valuation of raw materials; food analysis, and disputed points in regard to adulteration, labeling, and the enforcement of pure food laws; bacteriological and enzymatic examinations, including fermentation tests, pure yeast cultures, beverages of all kinds; development of chemical inventions and industrial processes; examinations and advice on special machinery.

Inquiries of a minor character will be answered on this page, while major matters involving personal investigations, analyses, etc., will, if desired, be treated confidentially through the mails. All questions, materials for analysis, or letters leading to the opening of negotiations for special work will receive prompt attention if addressed to

CHARLES B. DAVIS,
Care of "The Chemical Engineer," 118 East 28th Street,
New York City.

S. B. S.—According to the "Patents and Designs Bill" presented to the House of Commons on November 19, 1917, the inventor is expected to work his invention within four years, otherwise it will be subject to compulsory licences.

A. L.—Am pleased to know you have disposed of your chemicals and colors to the industries I mentioned in my last letter.

The working formula for the manufacture of methylene violet will be ready to forward to you in a few days.

C. A. B.—Your paper pulp on chemical analysis is found to consist of cotton and wood fibres. There is too high a content of resin and the starch reaction is also too pronounced.

Your alkali digestion has not been carried to the required point; also your washing process is very defective.

I would strongly advise you to ship me samples from the next few batches so that I may detect the source of your further troubles, should any arise; also to enable you to put out a more uniform product.

G. O. M.—Any product you wish to forward me for chemical analysis and reproduction will receive my individual attention. And as I mentioned in my letter, I am in a position to supply working formula and type and size of all chemical plant required.

D. T. A.—The readily oxidable mass you sent me is a pyrophoric cerium alloy, containing approximately 75% cerium. The cerium used for this type of alloy should be free from lanthanum, neodymium and proseodymium. If you wish to obtain an alloy of cerium and iron, having a eutectic point, the iron ingredient should not exceed 5%.

T. S. A.—Since your products contain tannin, convertible into black iron compounds, and since I find that your artesian well water is contaminated with ferric oxy hydrate, would advise your treating this water with sodium carbonate, which will not only remove this iron salt, but will also soften it and prevent the trouble you now have from incrustation in the boilers.

W. A.—All questions are answered free of charge unless they require special investigation, in which case only a small fee commensurate with the work involved will be asked.

No charge will be made for the matter you mention in your letter of recent date.

T. R. S.—Cellulose xanthate was discovered by Cross, Bevan and Beadle in 1892 and forms the basis for what is known as "Viscose Silk."

It is produced by the action of sodium hydrate, carbon disulphide, on cellulose. On dissolving this in water a golden brown syrup is obtained.

Their chemical formulae are expressed as:

$$\begin{array}{ll} (\text{Cell}) & \\ & \text{CS} \\ \text{NaS} & \end{array} \qquad \text{And} \qquad \begin{array}{ll} (\text{Cell}) & \\ & \text{CS} \\ \text{NaS}^2 & \end{array}$$

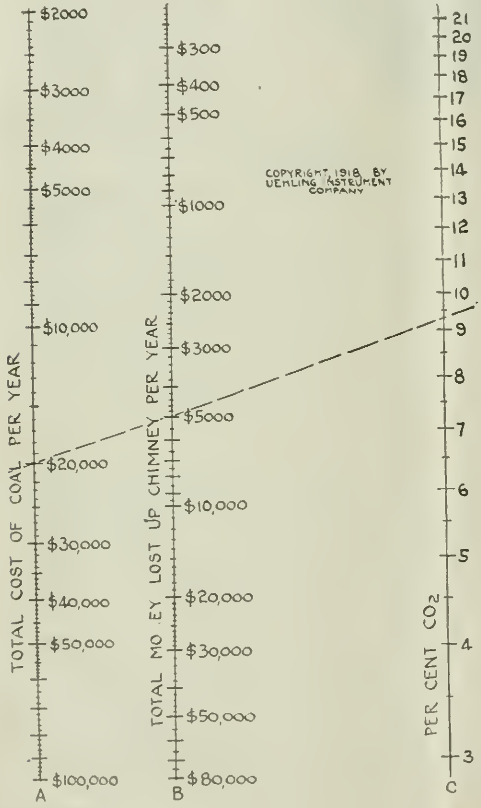
G. A.—The refrigerating apparatus and method you refer to in your last letter are protected by U. S. Patent 1,230,482, of June 19, 1917. Water is admitted intermittently to a vessel and caused to flow backwards and forwards in it. A current of air flows between the surface of the liquid and a parallel rotating surface, close to it, to vaporize the liquid. Air and vapor are then withdrawn by an exhauster; the vapor is condensed, and the air returned to the vessel.

Charles B. Davis.

Those whose inquiries to this department have not as yet received attention must bear in mind that unless replies by mail are specifically requested, communications can only be considered in the order of their receipt.—Editor.

This Chart Shows the Money Lost Up a Chimney

This handy and useful chart has been developed by the Uehling Instrument Co., New York. It is of unusual interest and value at the present time when the coal problem is so important, for it enables anyone to quickly and closely estimate the money now being lost up almost any chimney due to low CO_2.



Simply connect the percentage of CO_2 (shown in column C) with the money now being spent per year for coal (shown in Column A), and the intersection of the connecting line with column B immediately gives the dollars rolling out of the chimney in the form of heated gases.

Example: If $20,000 is spent per year for coal burned in a furnace whose average CO_2 registers 9.3%, what is the approximate money lost up the chimney per year?

Solution. Connect the $20,000 (column A) with the 9.3% (column C) as indicated by the dotted line drawn across this chart, and the intersection with column B shows the approximate yearly loss to be $5,000.

The object of this chart is to show that a high percentage of CO_2 is most desirable. To be sure, even where the CO_2 is as high as 21%, the theoretical maximum there is a loss, because in the average power plant the flue gases leaving the boiler have a temperature as high as 500 or 600° F. Loss therefore is inevitable unless a blower is used for exhausting the gases and some sort of interchange system is installed for either heating the feed water or preheating air and leading it under the grate.

It is well to know all about these various things and the Uehling Instrument Co. advises that its engineers will gladly co-operate in whatever way possible with responsible concerns to secure maximum returns from every dollar invested in coal. Being combustion specialists, the advice of the Uehling people will be of particular value in showing how to attain the highest possible percentage of CO_2. It should be borne in mind that combustion is a chemical process and for that reason should be studied from the viewpoint of the chemist.

It is significant that most of the large power plants of today have adopted CO_2 instruments that record automatically and continuously. The reason for this is to keep constant tab on the workers in the boiler room and the efficiency of combustion. The recorder may be placed at any convenient distance from the boiler in the office of the chief engineer, owner, manager or superintendent, while an auxiliary CO_2 indicator is placed on the boiler front in full view of the fireman. The function of the indicator is to keep the fireman constantly informed as to the efficiency of his own work. This feature is most commendable.

Coal cannot be saved by a CO_2 machine alone. If no attention is paid to the indicator or recorder, the installation of such apparatus borders on foolishness. The records should be carefully watched and studied and adjustments should constantly be made in firing methods until the best percentage of CO_2 is obtained. After the best mark is reached, fluctuation of the CO_2 line below that mark to any great extent should not be allowed.

This chart is based on a flue gas temperature of 600° F., and an outside air temperature of 60° F. Where the flue gas temperature is higher, or the outside air temperature lower, the money loss will be correspondingly increased. On the other hand, with a higher outside air temperature and a lower flue gas temperature, the money loss is proportionately decreased. Further, in the construction of this chart, it has been assumed that the coal has a calorific value of 14,500 B.t.u. per lb. of combustible.

It may also be interesting to point out that where there is only 3% of CO_2 in the flue gases, 76% of the heat value of the coal passes up the chimney as waste under the conditions outlined above. It is impossible, however, for these gases to contain as low as 2%, because it would require more than the original quantity of heat in the coal to heat the enormous surplus of air to a temperature of 600° F.

FOREIGN TRADE OPPORTUNITIES

These Opportunities for Foreign Business Relations Are Made Public by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce, Washington, D. C. Names, Addresses and Details May Be Obtained from the Bureau or Any of Its Branches. Refer to the Number of Each Opportunity and Place Inquiries for More Than One on Separate Sheets.

Rubber Goods.

26485.—An agency is desired by a man in France for the sale of rubber goods, and food products. Correspondence should be in French. Reference.

Sheet Celluloid.

26475.—An agency is desired by a man in Canada for the sale of white, opaque, and transparent sheet celluloid for making protractors, scientific instruments, and for advertising purposes. References.

Sulphur.

26086—A man in Portugal desires to purchase sulphur. Quotations should be made f. o. b. New York. Payment will be made against documents. Correspondence may be in English. References.

Metals and Chemicals.

26307—An exclusive agency is desired by a man in Italy from manufacturers of typewriters, adding machines, office supplies, calculating machines, metals, and chemicals. Reference.

General Chemicals.

26321.—A firm in Brazil desires to be placed in communication with American manufacturers and exporters of chemicals of all kinds. Samples, complete price lists, and full information should be submitted.

Natural Dyes.

26077—A man in France desires to purchase dyes derived chiefly from dyewoods, such as campeche, indigo, aniline, and others. Samples, catalogues, and price lists should be submitted. He would consider an agency proposition. Quotations should be made f. o. b. New York. Correspondence should be in French. References.

Dyes and Lubricating Oils.

26393.—An agency is desired by a man in France for the sale of dyes, lubricating oils, greases, leather, imitations of leather, steel, tin, twines, pipes, valves and fittings, wagons, petrol and paraffine, paper, and other products of common use. He will also make outright purchases, if necessary. Correspondence should be in French. Reference.

Chemical Products.

26441.—An agency is desired by a man in France for the sale of chemical products, metallic ores and heavy metals. Correspondence may be in English. Reference.

Coke Ovens and Accessories.

26396.—A man in France desires to purchase coke ovens and accessory apparatus for treating and compressing carbonic acid, a by-product of the combustion. Correspondence should be in French. Reference.

Chemical Products.

26416.—An agency is desired by a man in France for the sale of mechanical tools in general, sheet iron and piping, wrought iron, bolts, pins, etc., agricultural implements and tools, chemical products, in general. Correspondence should be in French. Reference.

Edible Colors, Chemicals.

26451.—A company in Canada desires to secure an agency for the sale of chemicals, hog stomach linings, calves stomachs, edible colors, tallows, greases, and bones. Quotations may be made f. o. b. point of shipment. Correspondence may be in English. Reference.

Sodium and Potassium Nitrates; Organic Acids.

26452.—A man in France desires to purchase or secure an agency for the sale of nitrate of soda, nitrate of potassium, superphosphates, dried blood, sulphate of copper, verdigris, tartaric acid, and citric acid. In case of purchase cash will be paid. If agency is granted, security will be given. Correspondence should be in French. Reference.

Various Chemicals and Leathers.

26317.—A business man in Norway, who will be in the United States until April 15, desires to secure agencies for the sale of chemicals of all kinds, leather of all kinds, and raw cotton. He desires, especially, to establish connections at the present time for the conduct of business at the close of the war. Payment will be made by cash against documents. Correspondence may be in English. References.

DISTILLATES

News Notes of Chemical and Allied Industries

New Aniline Works.

Colonial Aniline Works has been incorporated at Monticello, N. Y., with a capital of $10,000 by P. S. Glickstein and W. N. C. Loewenthal of Brooklyn.

Lieut. Davison Constructing Plant.

Lieut. A. W. Davison has been transferred from Washington, D. C., to Niagara Falls, N. Y., where he is supervising chemical plant construction at the works of the Oldbury Electro-Chemical Co.

Dr. Carruth Makes Change.

Dr. F. E. Carruth, who was formerly with the chemical division of the North Carolina Experiment Station, has become associated with the Schaefer Alkaloid Works, Maywood, N. J.

Lieut. Files Now Instructor.

Lieut. Ellery K. Files, of the Gas Defense Service, has been transferred from Washington to Yaphank, L. I., where he will act as an instructor at the National Army camp.

Managerial Duties for Frye.

Following the retirement of Robert C. Schroth, Jr., as president and manager of the Laboratory Supply Co., Columbus, Ohio, Paul W. Frye, secretary and treasurer of the company, is now acting manager also.

Huntington Studying Acids Situation.

W. D. Huntington of Baltimore, Md., who was recently elected chairman of the Acids Committee of the Chemical Alliance, Inc., has been spending several days each week in Washington in the interests of the committee.

Diamond Black Dyeing Co.

The Diamond Black Dyeing Co. has been incorporated at Passaic, N. J., with a capital of $10,000 by Isaac H. Lefkowitz, Frank McFadden, Alexander Black, of Brooklyn, and Peter Bippus of Astoria, N. Y.

$2,000,000 Oil Co. Incorporated.

With a capital of $2,000,000 the Hercules Oil Co. has been incorporated under the laws of Delaware by W. F. O'Keefe, G. G. Steigler and J. H. Dowdell of Wilmington.

Government Acetone Plant for New York.

Acetone for aeroplane wings will be manufactured by the U. S. government at Mechanicsville, N. Y., in a new chemical plant to be erected at a cost of $1,000,000. The plant will utilize by-products from the West Virginia Pulp & Paper Co.'s plant near by.

Blue Ridge Paint & Color Co.

The Blue Ridge Paint & Color Co., Allentown, Pa., has been incorporated with a capital of $10,000 to manufacture paints, varnishes, etc. A. W. Thompson is the principal incorporator.

Whitney Machine Co.

The Whitney Machine Co., Winchester, Mass., has been incorporated with a capital of $100,000 by Arthur E. Whitney, Robert F. Whitney and Walter C. Goddard, Winchester.

Stanfield Acquires Zinc Mines.

The Monkey Hill Zinc Mines, Kingdon Springs, Ark., have recently been acquired by E. N. Stanfield, Oklahoma City, Okla., who is planning for extensive developments.

Denver Concern to Rebuild.

Work will be started at once by the Chemical Products Co., Denver, Cal., to rebuild that portion of the plant which was recently destroyed by fire with an estimated loss of $50,000.

Butterworth-Judson to Build Addition.

At a cost of about $25,000 the Butterworth-Judson Corporation, manufacturers of chemicals, will erect a new one-story engine plant to augment its works in Roanoke St., Newark, N. J.

To Enlarge Plant.

The Philadelphia Paper Mfg. Co., Philadelphia, Pa., will spend $25,000 for extensive alterations and improvements to its plant to provide for increased business.

Chemical Preparations.

The Altrex Co., Chicago, Ill., has been incorporated under the laws of that state to manufacture chemical preparations. The incorporators are Chas. F. Brandel, Jas. E. Rainey and Walter Bashong.

Chemical Compounds.

To manufacture chemical compounds, etc., the United States Sanitary Products Corp. has been incorporated under the laws of Illinois with a capital of $100,000.

Brown, Saal Co.

To engage in the manufacture of chemicals and allied products, the Brown, Saal Co. New York, has been incorporated with a capital of $10,000 by W. C. Murphy, D. H. Cory and J. E. Saal, New York.

Bring Us Your Dyestuff Problems

The application of dyestuffs to textiles is as important as their production. The technique of this branch of the color industry has for years commanded the best talent among those dyestuff distributors who have catered to the highest class of trade.

An intimate knowledge of the possibilities of every dyestuff is often necessary to meet the particular requirements of the consumer. Dyeing is a chemical, not a mechanical, process, and the variation of local conditions, due to differences in quality of water, steam and chemicals, makes the dyehouse problem an individual one.

Such problems are welcomed by the technical department of this company, which is manned by chemists who have been picked because of their knowledge, practical experience and demonstrated ability. We have long maintained well-equipped laboratories at our different offices for this purpose, and invite inquiries and extend, without any obligation on the part of our customers, our services to all who stand in need of them.

A Chance to Spread the Truth—The Coal Tar Products Census

The digest of the U. S. Tariff Commission's census of coal tar products manufactured in this country during 1917, published in another part of this issue, will be read with the keenest interest by all who are in the slightest degree concerned with the advancement of the industry.

The outstanding, vital fact revealed is that American manufacturers have at least the long-hoped-for independence of foreign sources of supply practically within their grasp. While it is by no means to be supposed that the crisis is wholly past, or that we are as yet in a position to greet the thought of future competition with loud and derisive cackles, yet, from the standpoint of technical accomplishment the results are, perhaps, without parallel in industrial history. And certain it is that the American dyestuff industry is today able to stand upon its own feet and give effective battle against the threatened commercial onslaught.

At first blush the census would appear (to the general public) to indicate that the industry has "arrived." We are making, it says, as many pounds of artificial dyestuffs each year within our borders as we were wont to import each year before the war. In other words, we made nearly 46 million pounds here in 1917 where we imported nearly 46 million pounds in 1914.

Now this is the fact which will be blazoned forth in the newspaper headlines for the edification of the aforementioned and usually appreciative general public—which includes among its ranks the Patron of the Department Store. This means much to the future peace of mind of the dye manufacturer, for, if the reader of these headlines is careful and genuinely interested, he may read on and thereby learn that all is not gold that glitters. But the chances are that he has read much and often of the dye situation and has come, for reasons which will appear later, to regard all literature pertaining to it even as the now historic report of Mark Twain's death—greatly exaggerated! Therefore, there is a grand possibility that the headlines referred to will constitute the keynote and the essence of the general impression spread abroad.

The facts of the case, as further set forth in the detailed figures of the census, are that while the sum total of dyestuffs made here equals the former importations, yet in some instances the quantities of certain dyes produced here differs enormously from the quantities of these same dyes previously purchased from abroad. For example, the census shows that the quantity of synthetic indigo and the important alizarin and vat dyes derived from anthracene and carbazol was less than 3 per cent. of the quantity of these dyes formerly imported. This decrease in the total number of pounds of dyes available was, of course, offset by a corresponding increase in the production of other and less important colors.

This phase of the truth has long been known to the trade, but it happens to be the one phase which has most persistently escaped the notice of the public at large, who sought, in the face of optimistic reports from the manufacturers, an explanation of department store refusals to guarantee American colors. The seeker after knowledge was offered for consideration and reflection an apparent contradiction of facts, emanating from two distinct sources: (1) department store clerks told him, or her, that prices were up and American dyes could not be guaranteed because there was a great shortage and the colors obtainable were inferior to the German, and (2) he read that this country was making as many pounds of dyes as it formerly imported and that American colors were as good as the German.

The real reason for the unsatisfactory conditions, which was caused by the inevitable hiatus between the time of exhaustion of stocks of imported dyes left over when all shipments ceased and the time when the American manufacturers first began sending their products in quantities to the relief of the mills, has never been forced upon his understanding in such a way as to make it stick there long enough for him to explain the situation to one of his fellow creatures. Hence we have had a gradual weakening of confidence in public statements about the dye industry, partially buoyed up, it is true, by a patriotic willingness to believe anything good of it, but nevertheless resulting in the creation of a fertile field for German propaganda.

The dye manufacturers and the mill people know full well the makeshifts and artifices, the applications of certain dyes to fabrics for which they were never intended in the feverish desire to obtain results at any price, which followed as a matter of necessity and which must even yet, to a certain extent, obtain. It is an old story to them, but it is not an old story to the general public, despite all efforts to spread beneficent propaganda, and it is today furnishing the principal ground for the still alarmingly widespread belief that our manufacturers and chemists are going to prove unequal to their task.

This message must be driven home, once and for all, before it is too late, and the manufacturers and mill owners will do well to give the *modus operandi* their earnest consideration. Whether it can best be accomplished by advertising to or circularizing the department store heads, or by carefully worded statements to the press, or even by the maintenance of a publicity bureau charged with the task, is for them to decide. But the point is that they must get busy at once and see to it that fundamental facts, and not superficial conclusions, are what reach the public mind.

"Met. and Chem's." Loss.

R. C. Bergen, assistant editor of *Metallurgical and Chemical Engineering*, has resigned to go into chemical manufacturing work. He had been connected with that publication since 1915 and was formerly a chemical engineer with the Roessler & Hasslacher Chem. Co.

The Chemical Engineer wishes him every success in his new line of endeavor.

National Aniline in New Offices.

Following their determination to change headquarters, the entire personnel of the National Aniline & Chemical Co. are now installed in the company's own ten-story building at 21 Burling Slip, New York City. The company announces that in addition to consolidating and reorganizing its sales force, the business heretofore done by the Century Colors Corporation has been consoliated with the business and staff of the National concern, which owns the entire share stock of the Century Corporation.

The technical department of the National Aniline & Chemical Co. consists of the following: B. A. Ludwig, manager; Dr. Louis Joseph Matos, W. Ostern, W. R. Moorhouse, H. C. Merrill, Richard Doss and G. A. Schroeder.

Sidio Co. Opens New Factory.

The Sidio Company of America has opened a new factory in New York City for the manufacture of fused silica ware. Chemical engineers have found their large variety of funnels, breakers, trays, tubes, etc., of great assistance. A large portion of their product has already been contracted for by the government. The officers of the company are: F. H. Ruhe, President; W. Fensterer, Vice-President; G. H. Mueller, Secretary.

A New Chrome Brown.

A new fast Chrome Brown has been placed on the market by E. F. Drew & Co., Inc. (The H. G. McKerrow Department). This is made by the newly organized Knickerbocker Color Company.

It is of a rich, reddish brown character, requiring simply the addition of a slight toning of Alizarine Blue Black and the necessary admixture of white stock in order to give the regulation Government Olive Drab Shade. It is exceedingly fast to the specified light and fulling tests and is therefore an important contribution to the range of colors which are now being used for army cloths. It works either on a chrome mordant, with chrome in the bath, or on a top chrome method, and in addition to this gives an excellent mode shade of brown in an acid bath.

This is the first of a series of Chrome Colors to be made by this company on an entirely new method, and as it can be produced in quantity at a materially reduced scale of costs it will probably prove to be one of the most effective and least expensive colors on the market.

THE CHEMICAL POSSIBILITIES OF NATURAL GAS

By

Dr. J. B. GARNER *

In the early development of the natural gas industry little thought was given to faulty valves, gates, couplings, regulators and other appliances connected with the drilling, production, transmission and distribution of natural gas. A goodly proportion of the gas that was produced was lost for the reasons that the appliances used were faulty. The producer could easily see his potential profits dissipated into the air, and as the result of the situation, he was forced to go to the engineer to devise for him new and less wasteful methods of handling his gas. The value of the results of the work of the engineer along these lines was at once recognized because of the increased balance on the right side of the ledger. The producer was convinced that the engineer was a necessary adjunct to his business. Later on, when well pressures declined and it became necessary to install large compressing stations, gas cooling coils, etc., the need of the engineer became more and more apparent, because of the numerous mechanical and electrical problems which arose from the successful operation and maintenance of gas compressing stations. The most enterprising of these companies secured the services of highly trained as well as intensely practical scientific and technical men. There is no country on the face of the earth which is so highly specialized in the compression and transmission of high pressure gas.

A Valuable By-Product First Regarded as a Nuisance.

Simultaneously with the installation of machinery for the artificial compression of natural gas in order that it might be economically transported to market, there was a decided lowering of the pressure on the well. Perhaps as a consequence of the lowering of the well pressure it has since been discovered that some less volatile gas was obtained, and by the process of compression and the consequent cooling of the gas minor quantities of these less volatile hydrocarbons were sometimes deposited as liquid in the transportation lines. This usually took place in cold weather, and occasionally this liquid would collect at a low point in the line in association with quantities of water and would interfere with the transportation of the gas. At low temperatures the water would freeze and the result would be the bursting of the pipe line. Not only were large quantities of gas lost when this happened, but the service to the customers who needed the gas was interfered with at a particularly inopportune time. The deposit of these liquid hydrocarbons also sometimes injured the rubbers of the couplings to such an extent as to render it a nuisance to the producer. The producer therefore again consulted the engineer, and drips were devised in which the liquid deposited in the pipe line could be periodically removed without interfering with the transmission of the gas. The liquid hydrocarbons thus collected, when separated from the water, came to be known as drip gasoline. It was not obtained in quantities sufficient to render it an article of commerce, though quantities of it were sometimes sold to refineries.

The Work of Saybolt.

At about this time an enterprising and far-seeing chemical engineer, George M. Saybolt, conceived the idea, contrary to the general notion, that there might be enough of the heavier hydrocarbons existing in the form of vapor in natural gas to justify an effort for their commercial extraction in liquid form. Starting with this idea, Mr. Saybolt invented a method of extracting these vapors and engaged in a series of experiments under the auspices of a large natural gas producing company which interested itself in his work. The result of Mr. Saybolt's experiments was the conviction not only that gasoline could be extracted from natural gas, but that the process which he had invented was a highly successful one for that purpose. The first plant for obtaining gasoline by his method was installed and placed in operation in August, 1913, and soon another surprising fact was learned, namely, that the gasoline so obtained was one of a particularly high quality and different from any other then on the market.

You are all conversant with the growth and development of this remarkable natural gas gasoline industry. It is now perfectly apparent to any one connected with the natural gas industry that gasoline can be extracted in commercial quantities from natural gas and that adequate returns are to be had from the investment required. Ten years ago, however, the story was different. All of this progress, development and growth in this industry we owe to the pioneer efforts of the chemical engineer--George M. Saybolt.

Composition of Natural Gas.

Natural gas is composed almost entirely of paraffin hydrocarbons in varying proportions—methane, ethane,

---

* Extracts from a paper read before the annual meeting of the National Gas Association of America, at Pittsburgh, Pa., and published in the American Gas Engineering Journal.

propane, butane, pentane, hexane, heptane and octane. Nitrogen, carbon dioxide and helium may exist in small quantities. The first two of the hydrocarbons are fixed gases; that is, gases which liquefy only at very low temperatures and high pressures. Propane and butane are normally regarded as gases, but are intermediate in their properties between a true gas on the one hand and a true liquid on the other hand. Pentane, hexane, heptane and octane are normally liquids at atmospheric temperature and pressure. Most commonly methane is the predominating constituent and octane is the hydrocarbon, which occurs to the least extent in natural gas.

First Plant for Recovery of Natural Gas-Gasoline by Absorption Method.

I desire to direct the reader's attention, in the first place, to the processes which have for their purpose the separation of natural gas into its constituents; in the second place, to the chemical changes which natural gas as a mixture, or its constituents separately, will undergo when subjected to heat under varying conditions, and in the third place, to the change which the constituents of natural gas will undergo when subjected to chemical change in the presence of other substances with and without catalysts; and in the fourth place, to the valuable by-products which may be obtained by synthetic chemical reactions from the exhaust gas of gas engines.

Getting Amyl Acetate at Home.

Since August, 1913, when the Hope Natural Gas Company installed the first absorption gasoline plant for the recovery of gasoline from natural gas, the natural gas-gasoline industry has experienced a rapid and remarkable growth. There are in existence at the present time more than 100 plants in the United States with a conservatively estimated production for the year in 1918 of more than 90,000,000 gal. The extraction of gasoline by this method has in no way affected the value of natural gas as a fuel. It has made the production of natural gas more profitable; it has made the service to consumers more efficient, less interrupted and more satisfactory. It has been one of the most important factors devised or invented having to do with the conservation of our natural gas resources. Probably no other factor has been so noteworthy in this direction. It has not only utilized and saved that which was formerly wasted, but has enabled producers of motor fuel to meet the demands of the market for this material in a manner which would have been exceedingly difficult if at all possible in the present status of the oil industry. Petroleum distillates which of themselves are not utilizable as motor fuels are, when blended with natural gas-gasoline converted into satisfactory motor fuels. From the nature of the occurrence of gasoline as vapor in natural gas, one can readily understand why natural gas-gasoline contains relatively far more of the lower boiling hydrocarbons, pentane and hexane than is contained in refinery gasoline. It is the relatively large proportion of these two hydrocarbons that gives to natural gas-gasoline its greater value, and that has to the present time made it an article of great chemical importance.

At the outbreak of the present great world war, unusual chemical demands were made of American industry. One of the foremost of these demands was for explosives or munitions. Amyl acetate is extensively used in the explosive industries. Prior to the war, Germany furnished practically all the world's supply of this material. All that was made in America was made from amyl alcohol and acetic acid. A review of the patent literature discloses that there were numerous German patents by means of which this product could be prepared from pentane. American manufacturers, facing the shortage of this material, and knowing that the requirements would be great, went into the gasoline market, and asked that special cuts be made, so that they would be provided with sufficient pentane which they could utilize for the manufacture of this product. On account of the fact that the United States Government has been lax regarding exact disclosures in the patents granted, especially to Germans, it was necessary that American industry should employ skilled and competent chemists to endeavor to find a method by means of which amyl acetate could be manufactured at a reasonable cost and in sufficient quantities to meet present-day requirements. The work required of American chemists was rendered more difficult on account of the confusion which arose over incorrect disclosures in the patents already granted than if there had been no published data regarding any processes whatsoever. The whole ground had to be worked over thoroughly and carefully. As a result of the work of these chemists a process was invented, a plant was installed, and quantities of material adequate for all present-day demands produced. The Du Ponts at Wilmington, Del., have had in operation for two years a plant for this purpose. The process consists essentially of taking natural gas-gasoline and subjecting it to fractional distillation. The fraction which distills over at from 40 to 70 deg. C., and which is essentially a solution of pentane and hexane, is brought in contact with chlorine in the presence of ultra violet rays of light, until a certain amount of chlorine has been absorbed by this fraction. This chlorinated mixture is then subjected to a washing and distilling operation. In the distilling operation a fraction is selected whose chief constituent is amyl chloride, or pentane in which one hydrogen atom has been displaced by one chlorine atom. This amyl chloride is then mixed with sodium acetate and the mixture heated under pressure. Common salt and amyl acetate are the products of the change which occurs. The separation of these two compounds is readily and easily effected. Amyl acetate has the following commercial uses—solvent for pyrocollodion, collodion, photocotton and pyroxylene. Pyroxylene is used in the manufacture of artificial silk, imitation leather, waterproofing compositions, celluloid and photographic films. Pyroxylene lacquers and amyl acetate are used for metallic surface coverings.

The Demand for the Fatty Acids.

It appears to the writer that the chemical possibilities of hexane, heptane and octane are even greater commercially than those of pentane. One of the greatest of the demands made upon American industry, and, in fact, upon world industry since the beginning of this great war, is that of the fatty acids. The supply from living sources has not been equal to the demand, and industry, in order to meet the pressing requirements, has been compelled to look to mineral sources as a base of supply. Upon high authority the statement has been recently made, "It is not improbable that Germany to-day is supplying a large part of her fats from synthetic production, with mineral oils as a base of supply." It is entirely feasible by well-known and well-tested chemical reactions and methods of synthesis to prepare a fatty acid from these hydrocarbons that will have the same composition, same food value and same uses as the corresponding acid derived from natural fats. To have made the statement ten years ago that gasoline was a potential force in supplying a part of the food requirements of the nation would have been regarded as fanatical and impossible.

Benzol Formed by Chemical Change Which Occurs When Coal Is Heated.

Within the past year, many of the newspapers and most of the popular magazines have contained articles descriptive of the recovery from coal and coke-oven gas of benzol and toluol, and the manufacture from these substances of high explosives, important drugs and medicines, and a widely used coal-tar dye. These articles have appeared as a result of a desire on the part of the American people to learn of the demands which are being made upon American industry by the nations at war. Germany had formerly supplied practically the entire world with these substances, and when the German supply had been cut off, such a demand had been created that it was necessary that some nation not at war provide ways and means of meeting these requirements. Plants for the recovery of benzol and toluol from coke-oven gas have been installed throughout this country with such remarkable rapidity and on such a colossal scale that American industry can to-day, if called upon, furnish the entire requirements of these materials for the world on a war basis. The scientific investigation which preceded and has gone along with the development of this great American industry, shows clearly additional chemical possibilities which natural gas-gasoline may have. The mother substance of all the so-called coal-tar drugs, medicines, explosives and dyes is benzol. Benzol does not exist as such in coal from which coal or coke-oven gas is derived, but is formed by the chemical change which occurs under definite conditions when the coal is heated. It has been conclusively shown by a large number of chemists that when coal is caused to undergo chemical change at low temperatures, benzol or aromatic hydrocarbons are formed. I have mentioned previously in this paper that high-boiling paraffin petroleum distillates when heated to 500 to 550 deg. C. gave what is called "cracked" gasoline, and when heated to 650 to 750 deg. C. gave aromatic compounds. The writer has personally conducted experiments with propane and butane and the gasoline hydrocarbons under varying conditions of temperature in the presence of catalysts like nickel and iron, and found that benzol and toluol can be prepared from them. It seems therefore quite clear that if the proper time, attention and thought were put upon the problem, that a commercial process, economical and satisfactory, could be devised, whereby the hydrocarbons composing natural gas could be converted into benzol and toluol, or, in other words, if necessity required, natural gas-gasoline could be made the basis of the coal tar, drug, medicine, explosive, and dye industries.

Heavy Hydrocarbons.

It has long been noticed in the operation of absorption gasoline plants that there were heavy hydrocarbon vapors that were not condensed at atmospheric pressure by the condenser directly connected to the stills in the distilling operation. Early in the industry, these vapors were permitted to escape, either into the air or were passed into a low-pressure fuel line. Later on these vapors were collected and handled in a small compressor, and as a result of the compression and subsequent cooling, considerable yields of high gravity gasoline were secured. This practice is now a general one in absorption gasoline plants. The uncondensed gases from this tail house compressor have for the most part been either put into suction lines or into fuel lines. In some few instances, the compressor which is used on these vapors is a two-stage one, in which pressures of from 100 to 150 lb. are maintained on the discharge. When such compressors are used, the product produced in the second stage of the compression, or in the low stage if the pressure is above 50 lb., contains highly volatile liquid. If the liquid produced under such circumstances is trapped or blown off into run or storage tanks, the product undergoes weathering, which means nothing more or less than that the material is permitted to remain in the tanks until the highly volatile portion has evaporated. In the majority of these cases the weathering or evaporation products are permitted to escape into the air. This practice has been nothing more or less than criminal waste, for every producer of natural gas-gasoline has known that under no circumstances can this material be delivered to market in ordinary tank cars, and that although he has spent his money for equipment and power in producing it, he has received no financial return from it. It seems incredible that the commercial possibilities of extracting liquid by-products should have been unnoticed for so long a time.

Value of Butane Constituents.

As the natural gas-gasoline industry developed and its possibilities became well known, leaders in the natural gas industry, as a result of their studies in determining the best conditions of operation of gasoline plants, realized that there could be extracted from natural gas other by-products of a liquid nature, which were too highly volatile for use and shipment as gasoline. Recent discoveries have disclosed the utility and value of the propane and butane constituents of natural gas when they are substantially free from other constituents of the gas. A process has been devised for the recovery of these two substances in liquid form along with the recovery of gasoline from natural gas. The plant which will produce these two substances is made as an adjunct to the absorption gasoline plant. It can be easily and cheaply installed, and can be operated with very low operating cost as the operating conditions require no additional attention other than that which the men regularly employed on a gasoline plant can give to it without neglecting their other duties. One plant has already been installed for the manufacture of both liquid butane and propane. Since May 31, 1917, it has been possible to produce at this plant approximately 2,200 gal. of liquid butane and 2,000 gal. of liquid propane per day.

In practicing the process for the recovery of substantially pure liquid butane and liquid propane, the by-product vapors from the condenser consisting of a mixture of propane, butane, some pentane, hexane and fixed gases are passed under pressure under a definite set of conditions through an absorbent oil. This treatment is for the purpose of removing petane and hexane. The remaining vapors—substantially a mixture of propane and butane, are, under a given set of temperature conditions, subjected to pressure. This results in the condensation of a highly volatile liquid product from which liquid butane is commercially produced. The remaining uncondensed propane vapor is again subjected to a compressing and cooling operation, and a liquid portion is obtained, from which substantially pure liquid propane is obtained. The products as obtained by the process thus briefly described have the following average physical properties:

Liquid butane is a clear, colorless, mobile liquid with a gravity of 106 to 108 deg. B. at 32 deg. Fahr.; it has a heating value of about 3,400 B.t.u. per cubic foot. One gallon of the product when evaporated produces 37 cu. ft. of vapor when measured at 60 deg. Fahr. and atmospheric pressure. The gravity of the gas or vapor produced varies from 1.98 to 2.02, air equalling 1 The boiling point of the liquid at atmospheric pressure varies from approximately 29 to 34 deg. Fahr. The following temperature-pressure relations, when this product was confined in a steel cylinder, were found:

Degrees Fahr.	Pressure Gauge
44	55
60	65
71	83
81	98
92	112
103	129

Latent heat of evaporation at 1 atmosphere and 32 deg. Fahr. = 164 B.t.u. per pound.

Liquid propane is a clear, colorless, mobile liquid, gravity 128 to 131 deg. B. at 32 deg. Fahr. Heat value, 2,600 B.t.u. per cubic foot. One gallon of the product upon evaporation will yield 45 cu. ft. of gas or vapor at 60 deg. Fahr. and atmospheric pressure. The gravity of the gas produced is 1.51 to 1.54. The boiling point of the liquid at atmospheric pressure is approximately 49 deg. Fahr. The following temperature-pressure relations, when this product was confined in a steel cylinder, were found:

Degrees Fahr.	Pressure Gauge
47	438
59	453
70	470
81	500
91	524
100	555

Numerous practical and engineering tests have been made on both of these products. They have been found suitable for the lighting and heating of homes and buildings in regions remote from the gas fields. The ordinary commercial appliances in the way of burners and stoves have been used in these experiments. The readjustments which have been required in these common devices for the economical and satisfactory use of those products have been learned. Tests have been made with those gases as a source of power for stationary engines and automobiles. In the work of adapting these products for motor fuel purposes, the writer has had the hearty co-operation of Drs. Raymond F. Bacon and Harry Essex, of the Mellon Institute, and Mr. Barber, an experienced internal combustion engineer. The results of the work carried on clearly indicate and prove that not only can those substances be used with the ordinary equipment of internal combustion engines, but that the carburetor can be entirely done away with, and in its stead a gas mixer be used. The following road and maximum power tests will be of considerable interest:

RECORD OF ROAD TEST USING BUTANE AS FUEL JULY 9-10, 1917

Machine	Crawford 45 hp., using gas mixer in place of carburetor.
Weight	Empty 3,750 lb., loaded 4,750 lb.
Run consisted of	21 miles Pittsburgh city driving, 111 miles country-mountain driving.

Location of run	From Pittsburgh to the east side of Laurel Ridge (beyond Ligonier, Pa.) and return.
Gas supply	In three cylinders, containing 78 lb. of butane.
Total gas used	58 lb.
Total mileage	133 miles.
Miles per pound	2.3 miles.
Miles per gallon	11.5 miles.
Adjustments made	70.
Connections made	21.
Stops to change tanks, etc.	40.

Note.—Each stop necessitated readjustment and large loss of gas—unnecessary with proper tanks and purest gas.

Comparison with Gasoline.

The same Crawford car, equipped with Stromberg carburetor, on the same run with three stops gives 9.3 miles per gallon of 76 deg. gasoline.

With forty stops, and the same number of adjustments, the mileage would be less than 5 miles per gallon of gasoline.

In addition to this excellent mileage shown, the oil requirement was cut over 50 per cent. But 1 quart of oil was put into the system and not over ¾ quart used. Ordinarily with gasoline on this run, 2 quarts are necessary.

Remarks.

The run as recorded above was made on a very bad day. Rain fell hard for at least four of the ten hours time and the air temperature was from 52 to 60 deg., giving little chance for gasification by heat; also the roads was necessarily slippery.

The engine at no time failed to give the proper mixture and could be throttled down to 5 miles per hour on a 12 per cent. grade without stalling or missing a single explosion. This cannot be done with any four-cylinder car using gasoline.

In the maximum power tests which were conducted at the Mellon Institute, a Dodge motor was used. Various fuels were tested, and the total horsepower developed by all the fuels used did not vary from one another more than 1 per cent., or easily within the limits of experimental error. Carburetor adjusted and spark advanced to maximum power. The temperature of the exhaust gases varied from 640 as a minimum to 655 deg. C. as the maximum.

In our work with the stationary engines, we have found that 1 cu. ft. of propane is equivalent to almost 2¼ ft. of ordinary natural gas, and that 1 cu. ft. of butane is equivalent to approximately 3 cu. ft. of ordinary natural gas. This is the relationship which could have been anticipated from the relative heating values of the different products. In addition to the uses cited above for these by-product liquids, other important uses have been discovered and appliances for their satisfactory use commercially devised, namely, for the purpose of the cutting of metals and of incendiary bombs for offensive warfare work. The latter one of these uses will be omitted from the discussion of this paper for obvious reasons.

Fuel for Metal Cutting.

The credit for working out the details of the torch used for metal cutting is due to James and Harry Anderson, of the N. C. Davisson Burner Company. Liquid butane and liquid propane have both been successfully used by these same gentlemen for the welding of cast iron, aluminum and other metals. Work is in progress which has for its purpose the development of a torch which will enable these materials to be used for steel welding. The writer has every reason to believe that this torch will soon be available for sale on the American market. In accordance with the Interstate Commerce Commission specifications No. 6 for shipment of liquefied petroleum gas of not over 150 lb. charging pressures, cylinders may be used which are seamless, or of welded or brazed construction, and must show a test pressure of 600 lb. Butane does not require 150 lb. charging pressure. It is therefore possible to ship liquid butane in accordance with these specifications in cylinders which will weigh from one-eighth to one-third that of the cylinders now used in interstate commerce shipments of gases which are used for similar purposes. This gives butane a marked advantage in freight and express shipments. In addition, the cost of these cylinders should not be in excess of 40 per cent. of the other cylinders which are in use commercially.

Another added advantage in the use of butane is its remarkably narrow explosive range. The following may be of interest with reference to the explosive limits for mixtures of various commercial gases:

	Per cent. of gas
Natural gas	5.0 to 11.5
Methane	6.1 to 12.8
Coal gas	7.9 to 19.1
Acetylene	3.3 to 52.3
Hydrogen	9.45 to 66.4
Butane	3.0 to 8.0

It is clear from the above that butane is the safest to use of all commercial gases.

It is apparent from the above program that there are tremendous possibilities from the recovery and therefore the use of these liquids, highly volatile products of natural gas. A discussion of other possibilities of these substances is deferred to another section of the address.

Chemical Changes Which Natural Gas, as a Mixture, or Its Constituents Separately Will Undergo When Subjected to Heat.

Early in October of 1915 the writer, in connection with his assistants, began a preliminary study of the effect of heat on natural gas.

They made use of electrically heated fused quartz or Shelby steel tubes. Experiments were made both in the presence and absence of catalysts and the influence of these substances on the decomposition under temperature ranges of from 400 to 1,400 deg. C. studied. The catalysts used were pumice-nickel, pumice- copper, charcoal, finely divided copper, finely divided iron, aluminum, aluminum chloride, and silica. It was found that the decomposition, whatever took place in the presence of these catalysts, varied in a manner that was characteristic for each catalyst. For example, one catalyst, under a definite set of conditions, gave a high percentage of acetylene while another produced none.

There has been quite a lot of work done on the thermal decomposition of the paraffin hydrocarbons, but as far as the writer is concerned he is not aware of the industrial application of the results of the majority of this work. The patent, scientific and technical literature contains much information relative to the subject.

In the experimental work which the writer did the following products were used: (a) Natural gas as is delivered to the city of Pittsburgh; (b) vent tank gas; (c) propane, and (d) butane.

All of the samples of these gases were carefully analyzed and tested and their properties tabulated. The gases were then caused to pass through the apparatus provided for their study under varying conditions of temperature, pressure and rate.

In order that this paper may not be made tedious by the introduction of tabulations of results these have been omitted and will be published subsequently. It is sufficient, upon this occasion, to state that the experimental results were most gratifying in that the conditions of experimentation were learned whereby natural gas found chemical changes when subjected to heat under varying conditions. Carbon black, unsaturated hydrocarbons, of both the olefines and acetylene series, and hydrogen are the direct and only products which are obtained when one set of conditions is observed, while on the other hand, when another set of conditions is observed, in addition to the products mentioned, benzol, toluol, naphthalene, etc., are produced.

Industrial Application of Results.

The industrial application of the results of our experimental work has, so far, been confined to that set of conditions which had for its purpose the production of the greatest yield of the highest quality of carbon black. In the two plants which have been built the following are the representative results:

Kind of Gas	Ratio of Gas Passed to Gas Collected	Carbon Black Formed Lb. Per 1,000 Cu. Ft.	B.t.u. of Discharge Gas	B.t.u. of Inlet Gas	Per Cent. Unsaturated Hydorcarbon
Natural gas	1.27	4.52	840	1,142	6.75
Vent gas	1.42	6.44	861	1,347	12.9
Propane	2.63	26.9	866	2,600	26.2
Butane	2.99	38.2	702	3,400	26.6

It will be observed, first, that natural gas, as a mixture, gives a yield of barbon black three times as high as that usually obtained by the wasteful process of incomplete combustion, and that the yields from the other gases are far in excess of those obtainable from ordinary natural gas.

Second.—That the discharge gas is larger in volume than the inlet gas by ratios varying from 1.27 to 2.99. The heating value of the discharge gas is of necessity much lower in value than the inlet gas; however, the discharge gas has a heating value much superior to that of any artificial gas. The discharge gas is therefore a commercial one, and if carbon black is the only product desired this gas can be put into the usual channels for delivery to market.

Third.—That the discharge gas contains unsaturated hydrocarbons of the olefine series, mostly ethylene, and that the amount varies from 6.75 to 26.6 per cent. The olefine hydrocarbons are present in artificial gas, and in a large measure are responsible for its luminosity. If it is desired these unsaturated hydrocarbons may be used by simple chemical reactions for the manufacture of:

(a) Glycols.

(b) Industrial alcohol, acetaldehyde, acetic acid, acetone.

(c) Chlorinated olefine solvents.

It is well known in organic chemistry.

1. That members of the olefine series of hydrocarbons when treated under the proper conditions with potassium permangenate yields glycols.
2. That olefine hydrocarbons when treated under the proper conditions with sulphuric acid yield compounds which on treatment with water give alcohols and regenerate the sulphuric acid.
3. Olefine hydrocarbons when treated directly with chlorine absorb the chlorine chemically and yield chlorine derivatives.

The glycols are, as a general rule, thick, colorless liquids and have a sweet taste. They are miscible with water and alcohol in all proportions. Recently these substances have been utilized as substitutes for glycerin in the manufacture of medicine, drugs, explosives, etc.

The extensive commercial use of alcohol is too well known to need much discussion. The largest commercial uses of industrial alcohol are for solvent purposes. In the manufacture of organic dyes, varnishes, explosives, perfumes, tinctures, etc. Since the opening of the European war large demands have been made upon the alcohol industry for ether, acetaldehyde, acetic acid and acetone. All these substances may be obtained by simple well-known chemical reactions from industrial alcohol.

The chlorinated olefine derivatives have for the past few years been made in large quantities by other methods and have found extensive use in the rubber industry

I have pointed out above that carbon black and olefine hydrocarbons can be produced from natural gas or its constituents separately. I have further pointed out the chemical possibilities of the olefine hydrocarbons. If both carbon black and olefine hydrocarbons are recovered from natural gas and utilized in any of the ways mentioned above there is left a residue mostly composed of hydrogen. This residue can be easily converted into a practically pure product by subjecting it to heat at a temperature slightly in excess of 1,400 deg. C. The opportunity therefore is open for the manufacture of pure hydrogen from natural gas. Hydrogen, as is well known, is used largely in war times for balloon purposes; however, its largest peace time use is in the hydrogenation or hardening of oil. Tremendous quantities of cottonseed and other edible oils are readily converted by means of hydrogen in presence of nickel as catalyst into solid products or fats which have wide economic and industrial importance.

It can thus be seen that by the decomposition of the natural gas or its constituents separately, valuable products can be obtained which have almost unlimited possibilities.

Chemical Changes Which Natural Gas or Its Constituents Will Undergo When Subjected to Chemical Change in the Presence of Other Substances and Without Catalysts.

This section of the paper will be limited to the discussion of the chemical changes which occur when natural gas, or its constituents separately, are treated with the following reagents:

(a) Air, oxygen being the active component.

(b) Chlorine.

(*a*) *Reactions with Air or Oxygen.*

The use of material gas as a fuel is nothing more or less than the taking advantage of the heat evolved when natural gas reacts chemically with the oxygen of the air. The chemical change which occurs results in the conversion of the paraffin hydrocarbons of natural gas into carbon dioxide and water. The formation of carbon dioxide and water is the final result of a whole series of intermediate chemical changes. It is to these intermediate chemical changes that I desire to call your particular attention at this time. Considered from the theoretical viewpoint, methane, the predominating component of natural gas, should yield, when treated under the proper conditions with air or oxygen, the following substances: Methyl alcohol, formaldehyde, formic acid or carbon monoxide, carbon dioxide and water.

H. S. Blackmore, United States Patent No. 774,824, of Nov. 15, 1904, claims to have invented a process whereby methane when heated under a temperature of 260 deg. Fahr. with various metallic oxides as a source of oxygen obtains from 1,500 cu. ft. of methane, 125 lb. of methyl or wood alcohol, and at a temperature of 315 deg. Fahr., from 1,500 cu. ft. of methane produces 118 lb. of formaldehyde. The metallic oxide used as a source of oxygen were ferroso-ferric oxide, cupric oxide, and manganese and barium dioxides.

In United States Patent No. 891,753, another investigator has found that when methane is treated at temperatures from 86 to 122 deg. Fahr., with air in the presence of oak bark as catalyzer, he obtains from less than 1 cu. ft. of methane slightly less than 4 lb. of formaldehyde. He also claims that small quantities of methyl or wood alcohol and formic acid are produced. An abstract of this work may be found in the *Journal of the Society of the Chemical Industry*, Vol. 27, page 918.

Glock, in German Patent No. 109,014, claims that methane and air in equal volumes when passed through a tube containing granulated copper as a catalyst yields at a temperature of 112 deg. Fahr. formaldehyde in commercial quantities. Numerous other investigators, as Otto, Coquillon, Bone and Smith, and Bone and Wheeler, have made similar observations, viz., that methane in the presence of air and catalysts at certain temperatures yields formaldehyde.

Dennis and Hopkins, in the *Journal of the American Chemical Society*, Vol. 21, page 309, gives a description of a laboratory method of converting methane into carbon monoxide.

The writer has personally investigated the conversion of methane into carbon monoxide and finds that under the proper conditions, to wit: (a) Relative values of methane and air interacting; (b) presence of certain catalysts; (c) definite rate of flow, and (d) carefully regulated temperatures; that it is possible to convert methane into more than 90 per cent. of the theoretical quantity of carbon monoxide. This particular phase of the chemistry of methane was studied on account of the commercial importance of the following products which can be derived from carbon monoxide by simple chemical changes; (1) Carbonyl chloride or phosgene; (2) formic acide, and (3) oxalic acid.

Carbonyl chloride is used very extensively at the present time in offensive gas warfare and in the synthetic dye industry. It command a price which is quoted as nominal. This means that the product is difficult to obtain and then only at a good price. Formic and oxalic acid find ready sale at from 35 to 45 cents per pound in large containers.

Lemoine and Senderens, working independently, in 1907 found that when carbon monoxide and chlorine in equal volumes are passed through a suitably constructed apparatus containing wood charcoal as catalyst, react to produce quantitatively carbonyl chloride or phosgene. This is the commercial method of manufacture.

English Patents Nos. 4,684 and 9,008, French Patents Nos. 342,168 and 421,227, and numerous scientific articles describe processes for the manufacture of the salts of formic acid. These processes in the main consist of passing carbon monoxide in the presence of various catalysts at different temperatures into caustic soda, caustic potash and quick lime under some pressure to produce the salts of formic acid. These salts by simple treatment with sulphuric acid yield pure formic acid. This acid is manufactured on a large scale in Germany by this process.

If the salts of formic acid as prepared by the methods just given are heated to temperatures ranging from 680 to 770 deg. Fahr., these undergo chemical change resulting in the production of pure hydrogen and the salts of oxalic acid, from which oxalic acid can be derived by treatment with sulphuric acid. German Patent No. 229,853 is a description of a process wherein 1 per cent. of borax or 5 per cent. of boric acid is used as catalysts. The optimum temperature is as given above and the yield is 88 per cent. of the theoretical. German Patent No. 269,883 is a description of a process for the manufacture of oxalates from formates wherein the best temperature is given as 725 to 752 deg. Fahr. V. Merz and W. Weith, in *Berichte*, Vol. 15, page 1513, describe a process whereby sodium formates when heated out of contact of air at a temperature of 752 deg. Fahr. is converted into 70 per cent. of the theoretical quantity of oxalate.

The above instances of the chemical changes which occur when methane is burned either in the presence of air or oxygen, are given for the purpose of showing the state of the art. The speaker feels that it is entirely possible to develop commercial processes whereby the following substances may be produced from natural gas: Formaldehyde, formic acid, oxalic acid and carbonyl chloride.

(*b*) *Reactions with Chlorine.*

Since 1879 a great many chemists have devoted much time to a study of the problem of the chlorination of natural gas. Mallet has two patents on this subject—United States Patents Nos. 220,397 and 880,900. Professor Francis C. Phillips, of the University of Pittsburgh, has published more or less extensively on this subject in the *American Chemical Journal*. Elworthy holds French Patent 35,291 and German Patent 222,919, covering processes on this subject. Baskerville and Hamor, of the College of the City of New York, have done more or less extensive work in this field. McKay holds United States Patent 1,009,428. The subject, therefore, is one which has received more than passing attention. The industrial application of the reactions and processes described in any of the above mentioned literature or patents has not been made. In the fall of 1915 the speaker in conjunction with his assistants took up the study of this problem. The natural gas which was used was that furnished by the Equitable Gas Company to the Mellon Institute of the University of Pittsburgh. The chlorine used was liquid chlorine produced by the Electro Bleaching Company, of Niagara Falls, N. Y. The conditions of experimentation were varied from time to time until optimum conditions of operation were learned. It was found that when a mixture of natural gas (5 cu. ft.) and chlorine (4 cu. ft.) was passed through a tube at a temperature of from 518 to 554 deg. Fahr., using clay, pumice, infusorial earth, or luminum chloride as catalysts, that a reaction occurred smoothly and regularly, resulting in the production of the following substances: Methyl chloride, methylene chloride, chloroform, carbon tetrachloride and muriatic acid, together with small quantities of complex chlorinated hydrocarbons. Using the data derived from the laboratory work it was found by calculation that 1,000 cu. ft. of natural gas when treated with 526.4 lb. of chlorine will give:

51.34 lb. carbon tetrachloride, worth 15½ cents per pound.
189.8 lb. chloroform, worth 75 cents per pound.
62.86 lb. methylene chloride, market price nominal.
13.06 lb. methyl chloride, market price nominal, and
567.00 lb. muriatic acid, containing 37.9 per cent. of hydrogen chloride, worth 1¾ cents per pound.

Both methylene chloride and methyl chloride can be easily converted into chloroform and carbon tetrachloride by another simple reaction, using metallic iron or ferric chloride as catalysts and the yields of chloroform and carbon tetrachloride increased.

Chloroform a By-Product.

There are many gas fields in the United States and Canada which are not only remote from market, but which contain more than 9.5 per cent. methane, and would thus be suitable for the manufacture of chloroform, carbon tetrachloride and muriatic acid. In consideration of the fact that practically all of the chlorine on the market today is manufactured at points where there is cheap power, and that the gas spoken of is in regions remote from market, it would be necessary for any natural gas producing company manufacturing these chlorinated products to install a plant for the manufacture of chlorine. Caustic soda and hydrogen in large quantities would be produced by by-products, and these in turn would have to be disposed of or utilized profitably at the point of production. The success of industrial Germany along chemical lines is due to the fact that wherever an industry has been established and there are by-products resulting from this industry, additional processes have been installed or invested whereby nothing but finished products is obtained.

In other words, a program has been outlined which enables anyone owning natural gas in regions isolated or remote from market to install a series of processes by means of which all the natural gas can be utilized in a highly important and commercial way.

Not only have the chlorination reactions of natural gas, as a mixture, been studied, but particular attention has been paid to the chlorination of butane. On account of the fact that butane is a mother hydrocarbon of the following substances, butyl chloride and butylene chloride, it is from these substances that a large number of important commercial products are obtainable theoretically. Butyl chloride should, under the proper conditions of chemical change, such as are well known in the laboratory, yield butyl alcohol, butyl aldehyde, butyric acid and dipropylkatone. Butyric acid is the fatty acid derivable by saponification from butter fat. Dipropylkatone is a product which has the same commercial uses as acetone and many other additional uses in the explosive industry. Butylene chloride upon treatment with alkalies yields a hydrocarbon known as butadiene. This hydrocarbon is of practical interest, as it is the one which is the basis of the artificial rubber industry. In the *Journal of Metallurgical and Chemical Engineering* of May 1, 1917, pages 513 to 518, can be found an article giving a rather comprehensive statement of the chemical changes required to produce artificial rubber from butadiene. British patent No. 15,254 gives two methods of producing artificial caoutchouc. The methods are as follows:

1. Butadiene dissolved in benzol is heated ten hours at 150 deg. C. for a number of days.

2. Butadiene condensed at a low temperature by means of ether and carbon dioxide is kept in an autoclave at 90 to 100 deg. C. for four days. In both cases the solvents, unreacted upon material and by-products, are distilled off in vacuo or by steam, and a rubber-like mass remains.

Harries, in the *Annallen,* 1911, pages 157 and 383, describes another method whereby butadiene or its derivatives are heated with sodium wire. The yield is almost quantitative and the product obtained may be vulcanized quite readily. British patent No. 26,550 claims an advantage over the Harries process by conducting the operation in the presence of carbon dioxide. Matthews, in British patent No. 2,070, effects the same change in the presence of sulphuric dioxide. The process of Matthews is essentially as follows:

Butadiene or its derivatives are heated with sodium wire in the presence of benzol. Liquid sulphuridioxide is then added to the cooled solution and the mixture warmed in a sealed vessel at 40 deg. C. After some time the vessel is opened, when the solution is found to be very viscous and in some cases set to a jelly. On removal of the sulphur dioxide the product will be found to be elastic and to resemble natural caoutchouc.

The products soluble by the various methods are elastic, easily soluble in the ordinary rubber solvents, and capable of vulcanization. Many scientists are at work endeavoring to discover a process whereby artificial rubber may be produced at a cost which will enable it to compete with the natural product.

Developing a Process for Making Artificial Rubber.

The present status of the artificial rubber industry is much more promising than the artificial indigo industry was in its inception. The demand for indigo was relatively small, while the demand for rubber products has grown with remarkable rapidity along with the automobile industry. It is not to be expected that a synthesis so difficult and complicated as that of rubber could be effected without a great expenditure of time, energy and money. The ground work has been well laid, and I believe that American industry, which is to be at once the servant and master of world industry, will not be found wanting in supplying all that is needed to develop a process for the production of rubber. Natural gas, with its content of pentane and butane, which compounds can be readily and easily isolated, forms the hydrocarbon basis upon which the artificial rubber industry can be built.

Valuable By-products from the Exhaust Gas of the Gas Engine.

About the middle of the Seventeenth century Robert Boyle made the following statement:

> "The air is a confused aggregate of effluviums from such different bodies, that, though they all agree in constituting by their minuteness and various motions one great mass of matter, yet perhaps there is scarcely a more heterogeneous body in the world."

These words forcefully impress the fact that air is a mixture of several different gases. Oxygen, nitrogen, carbon dioxide and the rare or noble gases, are the main components of the atmosphere. Generally speaking the following is the average percentage composition of air, by volume, nitrogen, 78.03; oxygen, 20.99; rare or noble gases, 0.95; carbon dioxide, 0.03. Of the rare or noble gases argon exists in the largest quantity, 1,000 volumes of air contain approximately 9.37 volumes or less than 1 per cent. of argon.

When air is mixed with natural gas, and this mixture exploded in a gas engine, the hydrocarbons of natural gas react with the oxygen of the air to produce carbon dioxide and water vapor. The other constituents of air do not undergo any chemical change. The exhaust from a gas engine contains, therefore, nitrogen, the rare or noble gases, carbon dioxide, and water vapor. It is to these substances that I would have you pay particular attention at this time. If the exhaust gas is cooled by passage through coils sprayed with ordinary water and then compressed to a pressure of from 25 to 30 lb., practically all, if not all, of the water vapor present would be removed as liquid water. The remaining gas after such compression could then be treated according to a French patent of George Claude, for the recovery of carbon dioxide. In principle this process consists in passing the gas containing carbon dioxide through a body of liquid water under pressure, keeping the gravity of the water at such a point that practically all of the carbon dioxide is dissolved by the water at the temperature and pressure used. The unabsorbed gases consist of nitrogen and the rare or noble gases. The water containing the carbon dioxide dissolved under pressure can flow to a suitably constructed apparatus in which the pressure is lowered.

The carbon dioxide thus evolved can be picked up by a compressor and liquefied, and as such sold on the market for all the purposes as carbon dioxide prepared in other ways. R. F. Brownlee and R. H. Uhlinger have American patents No. 1,150,337 and No. 1,154,-

172, covering processes for the manufacture of carbon dioxide and nitrogen from natural gas.

In a preliminary report to the Ordnance Department of the War Department on the nitrogen industry by Charles L. Parsons, published in the *Journal of Industrial and Engineering Chemistry,* of September, 1917, pages 833 to 841, will be found a discussion of the methods utilized for the production of nitric acid and ammonia from the nitrogen of the air. Three of these processes—the Haber process, the cyanamid process and the cyanide process—all require practically pure atmospheric nitrogen.

The Haber process is a German one and consists of taking hydrogen and nitrogen and causing them to undergo chemical change at a temperatcre of about 500 deg. C. and at pressures from 125 to 150 atmospheres to form ammonia. This process is the one now mainly used in Germany. During the year 1917 the output by this process was equivalent to about 500,000 tons of ammonium sulphate. The ammonia obtained by this process can be oxidized and converted into nitric acid.

The cyanamid process is used quite extensively in both Europe and America. This process consists of heating calcium carbide to a red heat in the presence of nitrogen. The cyanamid produced is then powdered and mixed with sodium carbonate and lime, and the mixture treated with steam in large autoclaves to convert the nitrogen of the cyanamid into ammonia. In 1917 the German production of cyanamid was approximately 400,000,000 tons. Cyanamid is not only useful as a source of ammonia and ammonium compounds, but is well suited for use as a fertilizer when applied directly to the soil.

The cyanide process is, up to the present time, not a commercial success. The process consists of heating a mixture of sodium carbonate, ground coke or carbon in contact with finely divided iron to redness and then passing nitrogen through the mass. A reaction takes place rapidly, resulting in the formation of sodium cyanide.

Chemical Possibilities of Natural Gas.

It will be seen from the above that the nitrogen contained in the discharge gases from gas engines has many chemical possibilities in the production of compounds which are industrially very important.

Argon and the rare or noble gases, on account of the fact that these substances undergo no chemical change of any kind, will certainly be left in the residue gas after the recovery of carbon dioxide and the fixation of the nitrogen.

Raleigh was enabled to isolate argon and other rare gases from the atmosphere in 1893 by making use of the chemical inertia of these substances. Argon is a gas without color, taste or smell. It is incombustible and a non-supporter of combustion. Recently it has been shown that argon may find extensive use in the electric bulb industry.

The dawn of the day of the American industrial empire is upon us, and as the light of it breaks, the most splendid possibilities are revealed to us. In no field of commercial endeavor are its possibilties greater than in the industries having specifically to do with oil and gas. There are the possibilties of food for mankind and heat to prepare it for his growth and development. There is medicine to cure his ills and drown his sorrows; light to illumine his pathway and make it more cheery; materials to clothe, adorn and glorify the bodies of men. It is a most auspicious and prophetic time, and one which is worthy of the most serious and thoughtful consideration. It is the time above all times when men of vision and men of courage are needed. It is not an impossible time, but is one where the greatest of results may be realized if the efforts are properly directed. Subsidized chemical and engineering research is the keynote to the commercial realization of the possibilities of this age. The Natural Gas Men's Association can do its bit by entering upon a program of subsidized and heartily supported research.

Government Announces New Electric Furnace for Brass

Washington, D. C., May 31.—The U. S. Bureau of Mines today announced the perfection of a type of electric melting furnace that may be revolutionary in the making of brass. Patents of this furnace, known as the Rocking electric furnace, have been taken out by the bureau and have been assigned to Secretary of the Interior Lane as trustee. Free licenses to operate these furnaces under the patents, it is understood, can be obtained by making application through Van. H. Manning, Director of the Bureau of Mines.

The new furnace, which it is claimed will reduce the important losses in brass melting, is the result of five years' experimentation by H. W. Gillett, chemist of the Bureau of Mines, in cooperation with the laboratory of Cornell University, the American Institute of Metals and a number of manufacturers of brass.

Up to the present most brass has been made in costly crucibles of imported clay and graphite. Since the war it has been impossible to obtain the imported materials for crucibles, and manufacturers have had to put up with crucibles of much poorer quality, and at a cost many times that of prewar prices. With the huge tonnage of brass needed for war purposes, such as shells for cartridges, manufacturers have been anxious for a solution of the crucible problem. The bureau states it is inevitable that the next few years will see electric furnaces largely replacing crucible furnaces and that there will be a development comparable to that seen in the steel industry in the last few years. The electric furnace, it is also declared, will greatly decrease the loss of zinc which, together with copper, makes brass. Zinc boils at a much lower temperature than copper, and there have consequently been large losses in the open crucible furnace through volatiliza-

China as a Market for American Coal-Tar Colors

Throughout the world there has been, for several years past, a general recognition of the enormous possibilities of China as a market for a great variety of American and European manufactured products, as the country is opened to commerce and its consumptive power expands.

The German dyestuff trade was prompt to recognize these possibilities and had organized a very extensive distribution of its products prior to the war. In fact, China consumed about two-thirds of the artificial indigo exported from Germany.

Now China is turning to the United States for its supply of dyestuffs, and American color manufacturers are studying the peculiarities of Chinese trade. Sales of certain dyes have already reached respectable figures.

The following study by our consul-general of Hongkong furnishes an excellent picture of the Chinese trade in dyeing materials and how a market may be obtained for the American products:

There is no prejudice against American dyes. Most firms now in the business are British, and usually they prefer to handle British products. At the present time, however, British products in many lines are not to be had, and in any event, American dyes are as acceptable and popular as any other unknown dyes—and practically all of the dyes on the market at the present time are unknown compared with the German products imported before the war. An American representative of an American dye concern working in this market has sold well toward half a million dollars' worth of American dyes and, until competition from Europe comes, will doubtless sell more.| The trade here is reaching out for such products, and under normal conditions American-made dyes, when of proper quality, will have as good a chance in this field as any other dyes.

American manufacturers, however, have so far not been disposed or able to meet the terms under which Chinese users of dyes are accustomed to buy their materials, and the indications are that only by a complete grasp of the situation, viewed on a large scale, will American exporters permanently succeed in the business. The trade is so large and the American manufacturer's opportunity is so exceptional at this time that it is folly to consider the trade upon any other than a permanant basis. The fact is that the dye trade in the Far East (as measured by that of South China, at least), is one requiring large capital, thorough organization, and patient use of the highest merchandising ability.

Complete and definite figures as to the volume of the trade in Hongkong and South China are not to be had, for no Hongkong returns are available and a considerable portion of the trade was carried on with districts other than those included in the Chinese customs returns. Figures obtained from commercial sources place the quantity of aniline dyes sold in the Hongkong field in 1911 at 12,850,000 ounces, valued at about $225,000 Hongkong currency; in 1912, 14,500,000 ounces, valued at $433,000; and in 1913, 18,800,000 ounces, valued at $540,000 Hongkong currency. The sales of synthetic indigo in 1911 amounted to about 9,000 piculs (picul=133 1/3 pounds), valued at about $485,000 Hongkong currency; in 1912, to 8,860 piculs, valued at about $449,000, and in 1913, to 21,400 piculs, valued at about $1,128,000. These three years were the last years of normal trade. (The U. S. Treasury exchange value for the Hongkong dollar was about $0.42 in 1911; from $0.43 to $0.49 in 1912, and from $0.47 to $0.50 in 1913.)

In a general way, therefore, it may be said that the annual value of this trade in the Hongkong field is around a million dollars gold in normal years.

For all China the trade in aniline dyes and artificial indigo in 1913 reached $3,961,962 and $7,038,237 gold, respectively, or a total of $11,000,199. These imports were credited almost entirely to Germany and Belgium. The trade in fact was German trade.

The secret of German success lay as much in the German plan of merchandising as in scientific and economical methods of manufacture. There were several primary arrangements upon which all the German factories based their trade. One was the maintenance of large stocks of dyes on the spot—not only in large centers like Hongkong and Shanghai, but in all the principal cities and dye centers of China as well. A second was a system of sales on commission, i. e., the factory carried the stocks and risks, tided over all fluctuations in prices, bad seasons, and the like. Another was financial aid to dyeing establishments such as the large dye establishments the Chinese maintain in various centers for dyeing goods on a large scale. Still another was a graduated system of rebates on sales granted all agents in the shape of bonuses on quantities consumed; and, lastly, a general system of propaganda work, including not only advertising but the service of trained dyers and demonstrators and the like. This whole system was carried on by the factory, by the exporter. The dealer in Hongkong was in reality only an agent selling on commission.

The crux of the entire system was the maintenance of large stocks on hand—an arrangement that meant the locking up of considerable capital. How large the stocks of these dyes kept in China have been may be deduced from the fact that when the war in Europe broke out and the import of dyes from Germany ceased China at once began to re-export the stocks of dyes on hand.

In 1914, China imported aniline dyes to the value of $2,225,121 gold and re-exported them to the value of $24,188. In 1915, China imported aniline dyes to the value of $291,960 and re-exported them to the value of $1,759,737. In 1916, the imports were valued at $387,390 gold and the re-exports at $1,690,840. Imports of artificial indigo in 1914 were valued at $6,955,758 gold and re-exports at $16,551. In 1915, the imports were valued at $2,568,261 and the re-exports at $3,958,762 in gold. In 1916, the imports were valued at $340,821 gold and the re-exports at $374,969 gold.

Accordingly, there must have been on hand in China at the beginning of the war enough of a stock of aniline dyes and synthetic indigo to enable China to supply its own wants since that time (upon a restricted scale, of course), and export surplus stock to the value of over $4,000,000 gold, to which the stock on hand in Hongkong at the time should be added.

Most American manufacturers would be disposed to bear, or at least share, the burden of advertising and propaganda where contracts of purchase were such that they could receive the benefit of this advertising. Such benefit, however, hinges upon the establishing of recognized brands of dyes and upon a continuous and systematic sales system; for advertising without complete merchandising details usually is lost. A sales system in turn involves the use of trained men, not only salesmen from the United States or the factory generally, but Chinese salesman and experts trained in the use and sale of the products of a particular factory. Such an organization (assuming it is not possible to secure one ready made) represents years of efforts and expenditure. In this the Hongkong or Chinese importer can not bear the burden alone. Even if he is willing to advance the capital and brains to do the work, he can only do it under contracts protecting his work.

The fact is, in such lines as dyes and in such a field as China, this work is primarily the business of the manufacturer. After a manufacturer has established his goods here under his own "chops" or trade-marks, he can sell in the open market, as American exporters generally wish to sell at the present time. He can not do so in a permanent trade, however, until his goods are recognized. With the competition he will face after the war, the maker of dyes not known by a recognized "chop" will have no chance.

The Toluene Supply

A most important factor in connection with our vigorous prosecution of the war is the available supply of toluene to use in the manufacture of trinitro-toluene for high-explosive shells. The War Department estimates its needs for 1918 at 22,000,000 gallons, giving this figure as a minimum. The total annual production of toluene from American coke plants did not exceed 11,000,000 gallons in 1917. It has been necessary to plan on a large scale for "stripping" the aromatic hydrocarbons from ordinary illuminating gas, separating the toluene from the resultant mixture of benzene, toluene and xylene, and placing it at the service of the War Department. It is hoped, by this means, to secure most of the additional quantity required.

There are several important questions involved in the execution of this plan.

In the first place a recovery plant is a somewhat costly construction. Its usefulness would cease with the return to normal conditions. Gas companies hesitate to invest $300,000 or more in such an installation. This difficulty has been overcome by the readiness of the Government to assume any loss which may result from this score.

A much more complicated question is that connected with the basis for estimating the value of gas to consumers. The removal of the light oils from gas deprives it of its chief source of luminous power, but does not so seriously affect its thermal power. About 80 per cent. of the gas produced in our great cities is already used for heating purposes. The proposed changes would mean that the remaining 20 per cent should be utilized with incandescent mantles as a source of illumination. This involves further a change from the standard of candle power (ordinarily 22 candle power) to the standard British thermal units.

Discussion has centered upon the exact thermal standard which should be adopted as the equivalent of the heating power of the gas now currently produced, prices of gas to consumers remaining unchanged. In New York City the Public Service Commission has fixed 650 B. T. U. as a standard, while the gas companies urge a reduction to 585 B. T. U. In St. Louis the companies request a reduction from 600 to 575 B. T. U.

The question at issue is very clearly treated in the following statement by the Chairman of the New York Public Service Commission:

"The Commission upon its own resolution was holding a hearing to determine the advisability of changing the present candle power standard to the British thermal unit standard for the measurement of gas. The testimony adduced from the leading experts upon the subject had established the superiority of the British thermal unit standard, both scientifically and practically. While these hearings were in progress the Commission received a direct appeal from General Crozier, Chief of the Ordnance Department of the United States Army, setting forth the necessity that confronted the army in its need for toluol. Within twenty-four hours after a conference with General Crozier's representatives the Public Service Commission, on October 13, entered the order which will give freedom to the gas companies to change their standard of measurement so as to make practical the extraction of toluol. In my opinion, which was concurred in by all my fellow-Commissioners, it is stated:

"'A national emergency now confronts the Commission, which makes it imperative that, in the exercise of powers conferred upon the Commission, it take action more immediate than was originally contemplated to coordinate the industry of manufacturing and supplying gas in the City of New York to paramount national needs. Any delay in the action necessary to place the companies in a position to meet the requisition of the Government for a certain by-product of gas which can be recovered in sufficient quantity only if gas be manufactured under a thermal standard would jeopardize national interests. The Federal Government has made direct representations to the Commission that it is urgently necessary that the operations of the principal gas plants in this city and elsewhere be made available for the production of an important ingredient essential to war operations. To accomplish this it becomes necessary for the period of war to permit the gas companies to exercise the option of furnishing gas on a thermal basis.'

"The gas department of the Commission had made extensive tests, covering a period of eight months, to determine as nearly as it was scientifically ascertainable the thermal units of gas now furnished consumers under the present twenty-two candle power standard, as fixed by law. These tests and the testimony of experts led the Commission to fix 650 thermal units as that equivalent. The order of the Commission provided that if the thermal content of the gas is reduced below this equivalent by reason of the extraction of the by-product to meet the needs of the Government the price of the gas furnished to consumers shall be reduced by a discount in proportion to the decreased thermal conten. In other words, the consumer will pay for his gas at the same rate that he does today; if his gas should be reduced in quality, the price he pays will be correspondingly reduced.

"There can be no loss to the company by reason of this reduction, as the representatives of General Crozier assured me that the Government is prepared to make good any loss to the company, should there be any, and to pay for the installation of the necessary plants.

"The Commission by its decision, promptly meeting the needs of the Government, has conserved the interests of the consumers as well as those of the gas companies, who are free to complete their arrangements with the Government in the supply of toluol. OSCAR S. STRAUS,

"Chairman Public Service Commission."

Gradually the parties interested in the different centers of population, the representatives of the consumers of gas and of the producers of gas, are coming together in the patriotic effort to ensure the needed supply of toluene at the earliest date possible, and before long the gas of our cities will surrender its entire toluene content and be on a purely thermal basis—undoubtedly to the satisfaction of the manufacturers of incandescent mantles.

There is an interesting question in this connection which does not seem to have been raised, and that is as to the desirability of returning to the gas the benzene and the xylene stripped from it, along with toluene, after the latter has been separated by distillation. Such treatment would do much to raise the thermal value and bring it back nearly to its primary figure. A carburetting of this nature or by some analogous means, might be attempted to obviate any practical disadvantages resultant from the towering of thermal power in consequence of stripping.

It had been hoped that the Rittman process for making benzene and toluene from petroleum residues might be sufficiently advanced so as to contribute, to some extent, in meeting this emergency.

Unfortunately that is not the case. We must depend for the present on the production of our coke plants and our gas works.

T. H. N.

Poisoning from Trinitro-Toluene

The manufacture of trinitro-toluene in this country, for use in shells, has already assumed vast dimensions and will prospectively be doubled at an early date. There has been constant evidence of more or less poisoning among those engaged in making or handling the product. The "Journal of the American Medical Association" contained recently a study on the subject, in which the nature of the toxic action is carefully analyzed. It appears to stand in a direct relation to the extent of free ventilation in the factories where manufacture is carried on. Fumes are liberated by tinitro-toluene at as low a temperature as 32° C. (90° F.). If the circulation of air is defective symptoms of poisoning multiply. They lessen and practically disappear if thorough ventilation is maintained. This would lead to the assumption that the physiological action follows an inhalation of nitrous fumes. The recent investigations of Moore point, however, to the conclusion that the poisoning is caused by absorption through the skin of the compound itself. An oily condition of the hands seems to favor the absorption.

Personal susceptibility has some influence in determining the incidence of symptoms, and whether they appear after a short or after a considerable period of work. This is well shown in the case of dermatitis. But the amount of the exposure, or in other words, the dose of the poison, is the more important factor in producing the toxic effects.

The manufacture of trinitro-toluene in this country is mainly confined to a few firms, so that effective supervision can be planned. The loading of shells, on the other hand, is likely to be carried on by any manufacturer possessing the requisite facilities, which are comparatively simple.

In a paper on the safe handling of trinitro-toluene, read before the Section on Industrial Hygiene of the American Public Health Service, Surgeon Schereschewsky of the U. S. Public Health Service pointed out that the number of workers involved in loading operations is likely to be much greater than that concerned in the manufacture of this substance. Long contact with the production of other poisonous nitrated benzene products should have given manufacturers of trinitro-toluene the requisite experience to enable them to handle the manufacture of this substance with safety to the workers concerned. In addition to this, in the manufacture of trinitro-toluene, except at the final sieving and packing operations, the substance is handled either in closed containers or in a moist condition, under which circumstances the risk of poisoning is greatly reduced.

In loading operations, on the other hand, there is constant opportunity for nearly everyone connected with such work to become the subject of chronic poisoning through either the fumes or the dust of this substance. Valuable practicable points have been outlined by Schereschewsky in a recent number of Public Health Reports which should be in the hands of everyone interested.

The Distillation Products of American Lignite

There has been an increased amount of attention devoted during the past two years to the possibilities of American lignites. The great belt of lignite, occurring in Central Germany, has been exploited for many years. No less than 12 factories, employing over 1,200 workmen, are occupied with the systematic distillation of the lignite from these deposits and the recovery of the by-products. The residual coke is unfitted for metallurgical purposes, but serves admirably for the production of briquettes.

American chemists have felt that the time has arrived for utilizing the vast amounts of lignite found in our far western States, and making them as valuable national assets as is the case in Germany.

A plant was established in 1915, near Denver, with a daily capacity of 500 tons, and has been operating successfully upon Colorado lignite.

Professors H. K. Benson and L. L. Davis of the University of Washington have recently published in the *Journal of Industrial and Engineering Chemistry* (Vol. 9, p. 946) the results of a careful study of the distillation of a representative Washington lignite.

A series of comparative experiments showed that a temperature of 380° C. was the most favorable for the production of tar. At this temperature one ton of lignite yields 108 pounds of tar, or about 5.5 per cent. This tar shows a great similarity to petroleum or shale oil and has but little in common with ordinary coal tar. There is an entire absence of benzene and its homologues. One-third of the tar is soluble in alkalis. The solution thus obtained is free from phenol, although containing cresols and higher homologues.

The oils, obtained by the distillation of the tar, belong chiefly to the paraffin series, and can be used as solvents, lubricants, for motor fuel, etc. Seven pounds of paraffin wax are yielded by one ton of lignite.

The gas evolved is relatively small in amount at 380°, and low in thermal value. The yield of ammonia is about 4 pounds per ton at this temperature. The residual coke is 54 per cent. of the weight of lignite.

Distillation at higher temperatures increases the quantity of gas and ammonia, while lowering the yields of tar and coke.

The results of this preliminary work show that our western lignites cannot be expected to play any pronounced rôle in supplying the crude materials formed by the distillation of bituminous coal. Undoubtedly their complete utilization by distillation and collection of the by-products is most desirable. Our sources of combined nitrogen and of motor fuel will be materially augmented, while the value of a large supply of cheap gaseous and briquette fuel will count for much in the industrial expansion of the West.

The Manufacture of Dimethylaniline and of Diphenylamine

Among the derivatives of aniline employed in the manufacture of colors dimethyl-aniline and diphenylamine stand in the forefront. A recent issue of "The Dyer and Calico Printer" contains a valuable study by Dr. E. Grandmougin on the current French practice in the production of the two intermediates, from which we quote the following:

Dimethylaniline.

Dimethylaniline was discovered in 1861 by the French chemist, Bardy, and prepared on a commercial scale for the first time in the Porrier works at St. Denis. The inventor's process is still used, the alkylation of aniline in the presence of a mineral acid. The only variation that has been made is that it has been found advantageous to replace the hydrochloric acid originally used by sulfuric acid. The reaction which takes place can be explained in different ways. Nevertheless, it seems almost certain that, to begin with, methyl chloride or methyl sulphate is formed, which, reacting on the aniline, produces, first, methylaniline and then dimethylaniline.

On the other hand, the action of sulfuric acid in methyl alcohol generates methyl ether, which is gaseous at the ordinary temperature and produces a considerable pressure. In order to attain the temperature necessary for the reaction, the process is effected in autoclaves, and this requires special precaution.

Formerly the autoclaves were constructed of cast iron. Now they are made preferably of steel, and to avoid the attack of the acid they are lined with enamel, or a special metal resisting acid. The space between the lining and the autoclave is filled with melted lead.

Each autoclave is of 300-litre capacity, and is charged with 80 kilos of aniline, 78 kilos of methyl alcohol, and 8 kilos of sulfuric acid at 66° Bé. The night before the work is to be done, the sulfuric acid and methyl alcohol are mixed in two portions. Two carboys are charged with 39 kilos of methyl alcohol each and 4 kilos of sulfuric acid are slowly poured in to each carboy.

The morning of the operation, the autoclave is charged by pouring in, to begin with, half of the aniline, that is, 40 kilos, then adding the methly alcohol and sulfuric acid already mixed as described, and then the second 40 kilos of the aniline. The autoclaves are charged and ready for work by about ten in the morning, then are heated up gradually to a temperature of 230° to 235° C. The pressure rises at the same time. At about two in the afternoon it has attained 30 kilos (67 lbs.), and is kept at this throughout the operation. About eleven in the evening the heat is shut off, and the autoclave is allowed to cool until the next day.

When the temperature has become normal, the pressure is released by allowing the gases to pass into a condenser to recover the methyl alcohol. Then by means of compressed air the contents of the autoclave are passed into a still. The amount passed in is regulated by the size of the still, and the autoclave may be emptied in successive portions—six, for instance.

Caustic soda has already been introduced into the still to liberate the dimethyl-aniline, which is in the form of sulphate. Steam is then introduced into the still, the methyl alcohol passes over first and is condensed apart. Then dimethyl-aniline passes over with the water, which is collected in a separator. After separation from the water, it is stocked in iron drums. There is no necessity ordinarily to redistill it. If for some reason this has to be done, it is distilled in the same manner as aniline, preferably in a vacuum.

On an average the yield is 98 kilos for the proportions indicated. Although to carry over the dimethylaniline six parts of steam suffice, theoretically, for one part of the base, practically at least three times as much steam is necessary, and this must be taken into account in calculating the cost.

In the pure state dimethyl-aniline distils at 102° C. The specific gravity is 96 at 15° C.

The purity of dimethyl-aniline is controlled by distillation. It should pass over between 191° and 193° C. to detect the presence of methyl-aniline, it is tested with acetic anhydride. There should be no rise of temperature when 10 c.c. of dimethyl-aniline and 3 c.c. of acetic anhydride are mixed at the same temperature.

The aniline used in the manufactur should be very pure, and should not contain more than ½ per cent. of water. Its specific gravity should be from 1.026 to 1.027 at 15° C. It should distill between 182.4° and 182.8° C.

The methyl alcohol employed must be free from acetone, which would lead to exaggerated pressure. The following calculation is valuable merely as an estimate giving the approximate cost of the manufacture of dimethyl-aniline before the war: 80 kilos aniline, 80. 00 fr.; 78 kilos methyl alcohol, 90.00 fr.; 8 kilos sulfuric acid, 0.50 fr.; 8 kilos caustic soda, 2.10 fr.: 1,800 kilos steam, 5·40 fr. 100 kilos of dimethyl-aniline would cost 178.00 fr. or $15.00 per 100 lbs.

Dimethyl-aniline was sold at 200 francs per 100 kilos before the war.

Dimethyl-aniline can also be made with methyl chloride, which is a by-product in sugar making. As this can be obtained by the action of chlorine on methyl alcohol, it might be an advantageous process after the war in order to use up the chlorine, of which there will be heavy stocks. The method is worked at St. Denis, by Vve. Brigonnet et Fils.

An autoclave with a double jacket is fitted with an agitator capable of making 125 to 130 turns per minute. This is charged with 50 kilos of aniline and 40 kilos of quick lime, slaked to 75 litres, and heated to 100° C. Then 62 kilos of methyl chloride are introduced gradually, taking two hours in making this addition. The pressure is maintained at 5 to 6 atmospheres.

At the close the pressure is lowered to 2½ atmospheres, and the contents of the autoclave are passed into a still by means of compressed air. In this the dimethyl-aniline is distilled over by means of steam. The yield is 116 to 120 per cent. of the weight of aniline. The operation is very rapid, and the autoclave may easily be charged twice in one day.

The uses of dimethyl-aniline are very numerous. Notably it serves as material for the manufacture of Methyl Violet, Malachite Green, Meldola's Blue, Methylene Blue, and other basic colors.

Other Methyl and Ethyl Derivatives.

Methyl-aniline is prepared in the same manner as dimethyl-aniline, but with a smaller proportion of methyl alcohol. For 100 kilos of aniline salt, 32 kilos of methyl alcohol are used, and the mixture is kept at 180° C. for ten hours. At the termination of the reaction, the product is made alkaline by means of lime, and the methyl-aniline is distilled with steam in the manner already described.

The product obtained contains about 90 per cent. of methyl-aniline. The balance is 6 to 7 per cent. of dimethyl-aniline and a little unchanged aniline.

Pure methyl-aniline is a colorless liquid, boiling at 192° C., and has a specific gravity of ·976·at 15° C. By acylation it gives methyl-acetanilide (exalgine), melting at 102° C.

Replacing the methyl alcohol by ethyl alcohol, ethyl-aniline and diethyl-aniline can be prepared. It must be noted, however, that in preparing diethyl-aniline with sulfuric acid, aniline hydrochloride must be used.

Ethyl-aniline boils at 204° C., and has a specific gravity of .94 at 18° C. Diethyl-aniline distils at 213.5° C., and its specific gravity is .936 at 18° C.

Diphenylamine.

To prepare this base, and other aromatic secondary amines, the process invented by Girard and de Laire is used. This depends upon the action of the salts of the amine on the amine according to the following quation:

R = pehenyl, etc, $R.NH_2 + R.NH_2HCl = R.NH.R + NH_4Cl$

This process is applicable homologues and mixed derivatives. Phenols may also be used:

$$R.OH + R.NH_2 = R.NH.R + H_2O$$

This reaction is not employed in the case of diphenylamine. It serves, for instance, for the preparation of diphenylmetaphenylenediamine, with resorcin and aniline, and of phenylnaphthylamines with naphthols and aniline, and of similar products. All these reactions are effected at a high temperature and under pressure.

The extensive use of the derivatives of diphenylamine has brought about a new method of synthesis at a lower temperature. They are often prepared also by reduction of the corresponding indamines and indophenols which are themselves produced by the oxidation of paraphenylenediamines. The indophenols can also be synthesised by condensation of the nitrosophenols with the amines in the presence of sulfuric acid. This process is simply a variation of the one already mentioned.

As already stated, diphenylamine is prepared still by Girard and de Laire's process. The operation is carried out in an autoclave which is lined with enamelled metal unattackable by acids, or the autoclave may be of earthenware, which is heated preferably, not in an oil bath but in a bath of an alloy,—30 per cent. tin and 70 per cent. lead, for instance.

As an example, 70 kilos of aniline salt and 50 kilos of aniline are heated to 260° C. This temperature is maintained for twelve hours, then the contents of the autoclave are allowed to cool. The operation is controlled by noting the pressure indicated by the manometer,—about 3 to 4 kilos. The complete operation takes 24 hours.

It is essential to use an anhydrous aniline salt and aniline free from water. It is evident that aniline and hydrochloric acid may be mixed in the desired proportion, distilled in a vacuum and dried; then the necessary proportion of aniline is added and the mixture is poured into the autoclave. Aniline salt is soluble in warm aniline.

The operation completed, the mixture is poured into a vat and boiled with hydrochloric acid in order to remove the aniline in excess. The cake of melted diphenylamine is then treated with boiling water, next with dilute soda, and again with boiling water. The operation is terminated by distilling the diphenylamine, preferably with the use of a vacuum. Water and a little aniline pass over at first, then diphenylamine. A little tar remains in the retort. Another way is simply to pour the mixture into water to remove the aniline salts and the ammonium chloride, following this by separating the aniline from the diphenylamine by fractional distillation. The yield may reach 80 percent. The untransformed aniline is recovered and used again. An important amount of the ammonia formed can also be recovered.

Commercial diphenylamine is usually sent out in compact yellowish blocks with a characteristic odor. It is fusible at 54° C., and distills at 310° C. To obtain it in a crystalline state, it is crystallized from alcohol or acetic acid forming white crystals.

The following calculation of pre-war prices allows an idea to be formed of the cost of production:

70 kilos aniline salt, 65.00 fr.; 50 kilos aniline, 50.00 fr.; 70 kilos diphenylamine, 116·fr.

This makes 165 francs per 100 kilos of diphenylamine for material alone, or $14.50 per 100 lbs.

INORGANIC CHEMICAL SYNONYMS

A Novel Work of Reference for Student and Chemist

By

ELTON R. DARLING*

Although Intended Primarily for the Student, It Is Believed that the Following Compilation of the Various Terms Employed to Designate Inorganic Chemicals Used in the Industries Will Prove a Convenience to the Experienced Chemist. The Writer Claims No Originality for the Synonyms, but Only the Bibliographical Research of the Material at Hand. The list will be completed in the next issue.

PART V

Nickel, 58.68.

It has a specific gravity of 8.7. It has a melting point of 1,450° C. It has a valency of two in the nickelous condition, and four in the nickelic condition.

Our first knowledge of nickel is found in the writing of Hiarni, who in 1694 speaks of it as "false copper." It was so called because although, possessing the color of copper ore, the metal could not, however, be separated from it. In 1751 Cronstedt published an investigation on an ore from the Helsingland mines. He obtained a salt which gave a green vitriol and a hard brittle metal. In 1754 he wrote of it as a semi-metal and called it nickel.

His views were not accepted until 1774, when Bergman's researches confirmed his work.

Sodium, 23.00.

It has a specific gravity of 0.9735. It melts at 97.3° C. and boils at 877.5° C. The valency is one.

It is to the Old Testament that we turn for our history of the sodium compounds. There reference is made to sodium carbonate, although it was then called "Nether." In Egypt it was called "Flos Satis." Down through the ages the salts of sodium were common, and much use was made of them. It was not, however, until 1807 that Davy prepared the metallic Sodium.

Technical Men Unite for War Work

Representing an effort to cooperate effectively and vigorously for war work, an important joint war committee has been formed by representatives of technical societies centered in Chicago. The movement was started by the Military Committee of the Western Society of Engineers, and, at the invitation of that committee, several meetings have been held at the Chicago Engineers' Club. As the result, the "War Committee, Technical Societies of Chicago," to quote the official name, was organized June 4, 1918.

The purpose of this organization is "to enable the technical societies of the Chicago zone to call into play the efforts of the members of the various societies herein represented as occasion may arise, and to coordinate their activities in the most effectual manner to help win the war." It is not proposed to attempt any novel "stunts" but rather to place at the disposal of the United States Government, and other authorized agencies, the combined strength and resources of the Chicago technical societies for war work, as need may arise.

The following member societies are cooperating in the new War Committee:

Western Society of Engineers.
Structural Engineers' Association of Illinois.
Society of Industrial Engineers.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS.*

PART XIV

Stability Test for Smokeless Powder.

Exposure to ultra violet light considerably accelerates the spontaneous decomposition of smokeless explosives, and this can be made the basis of a useful stability test. Explosives which were examined in this manner by *Berthelot* and *Guadechon* (Compt. rend., 1911, 153, 1220) were cut into cylinders weighing 0.25-0.45 gram, placed over mercury in a quartz tube, containing nitrogen or carbon dioxide, and exposed to the radiation from a quartz mercury lamp at a distance of 78-80 mm. for 6 hours. In all cases rapid decomposition occurred with production of carbon monoxide or dioxide, nitrogen, and frequently nitrous and nitric oxides. Powders consisting only of nitrated cellulose were found to be more stable than those containing nitro-glycerine. An English cordite containing 30% of the latter and 5% of vaseline, exposed in 1 c.c. of carbon dioxide, gave a mixture composed of the following volumes of gases: CO_2, 1 c.c.; CO, 0.17 c.c.; NO, 0.10 c.c.; N_2O, 0.02 c.c; N_2, 0.10 c.c. Numerical results are also given for the French A and B powders and for balistite of different ages and with different stabilisers. (See also Compt. rend. 1912, 152, 514).

Formaldehyde.

According to *Berthelot* and *Gaudechon* (Compt. rend., 1912, 154, 1803) a concentrated aqueous solution of formaldehyde is decomposed by the light from a quartz mercury lamp, even when the rays of wavelength less than 0.19 μ are cut off. The products of decomposition consist of a mixture in almost equal volumes of carbon monoxide and hydrogen, together with some (10%) methane and carbon dioxide. Sunlight also slowly brings about the same decomposition. Formaldehyde cannot be synthesised from a mixture of carbon monoxide and hydrogen by the action of sunlight, even in the presence of catalysts, such as spongy platinum, although it is formed to some extent when the mixture is exposed to the ultra violet rays from a quartz-mercury lamp. In the photochemical reaction, $CO + H_2 \quad CH_2O$, the equilibrium point is more markedly on the side of the decomposition products than it is in the case of the reactions $2H_2O \quad 2H_2 + O_2$ and $2CO_2 \quad 2CO + O_2$.

Higher Aldehydes.

When formaldehyde solutions are exposed to the radiation from a quartz-mercury lamp, according to *Pollitzer* (Monatsh., 1913, 34, 797) they undergo partial decomposition into carbon monoxide, carbon dioxide, hydrogen and methane, and partial polymerisation to glycolaldehyde and higher products. The higher aldehydes have been observed to form carbon monoxide, hydrogen, and the hydrocarbon corresponding with the radical to which the aldehyde group was previously attached. A re-investigation of the behavior of the homologues of formaldehyde indicates that they decompose mainly according to the equation $R.CHO = RH + CO$; at the same time condensation takes place to some extent accompanied by polymerisation to resinous substances; no pure condensation product could be isolated. Under the conditions of the experiments, in which moisture and atmospheric oxygen were excluded, no formation of acids or of esters could be detected, so that the earlier suggestion of Primbram and Franke that the formic acid obtained in the illumination of formaldehyde solution is produced by the hydrolysis of previously formed methyl formate is hardly probable. From the behavior of crotonaldehyde, which, like benzaldehyde and cinnamaldehyde, gives practically no liberation of gas, it appears that the decomposition expressed by the above equation is characteristic of the saturated aliphatic aldehydes.

The aldehyde under examination was contained in a quartz flask of approximately 100 c.c. capacity which was filled to the neck, any evolved gas being collected over water or mercury; the mercury lamp was at a distance of 2 to 3 mm. from the flask, but the temperature of the aldehyde never exceeded 50°. The substances examined were heptaldehyde, isobutaldehyde, propaldehyde, acetaldehyde, crotonaldehyde, benzaldehyde, and cinnamaldehyde. Crotonaldehyde gave only the formation of a resinous substance, while the two aromatic aldehydes gave merely red, nonvolatile products. Only a relatively small proportion of each aldehyde underwent conversion, although the illumination ranged from one to ten days in various cases.

Acetaldehyde.

A more detailed study of the photolysis of acetaldehyde has been made by *Berthelot* and *Gaudechon* (Compt. rend., 1913, 156, 233) who state that initial ultra violet rays do not convert the aldehyde into acetic acid in the absence of oxygen. Under the influence of medium and extreme rays oxidation takes place even in the absence of oxygen, a portion of the aldehyde being converted into acetic acid. The amount of acid produced is far greater when the aldehyde is in the form of vapor than when it is liquid. With rays (λ 0.25μ) polymerisation is rapid, both para and meta acetaldehyde being formed. No resinification results from the action of initial ultra violet rays, and it is only slowly produced by the medium and extreme rays. The presence of water checks polymerisation and resinification, but favors acidification, formic acid being formed in this case and in amount almost equal to that of the acetic acid.

Terephthalaldehyde.

Although terephthalaldehyde is very stable in the solid state and in solution in benzene in the dark, *Suida* (Monatsh., 1912, 33, 1173; J. Chem. Soc., 1913, Abs., 104, i, 52) states that its solution undergoes rapid atmospheric oxidation when illuminated by a mercury lamp, and a white crystalline deposit is formed. The deposit consists of terephthalaldehydic acid to the extent of roughly two-thirds, the remainder being terephthalic acid. The solution from which the crystals have separated gives a peroxide reaction with acidified potassium iodide solution. This oxidation of terephthalaldehyde appears not to occur at all if light is excluded, and it is not accelerated by the presence of nitrobenzene, in fact this substance exerts a hindering effect. A comparison with benzaldehyde seems to indicate that, assuming the supply of oxygen by diffusion to be more than sufficient, the oxidation velocity of each aldehyde group in terephthalaldehyde is considerably diminished by the presence of a similar group in the para-position. By interposing solutions of potassium chromate and of quinine sulphate between the solution and the source of light, it is discovered that the effect is mainly due to the ultra violet rays, but that yellow and red light can cause the oxidation to occur, although only very feebly. Spectrographic examination indicates that the effective rays are from 400 to 300 $\mu\mu$.

Nitrobenzaldehyde.

According to *Weigert* and *Kummerer* (Ber. 1913, 46, 1207) the transformation of o-nitrobenzaldehyde into o-nitrosobenzoic acid under the influence of light is independent of air and is a simple case of isomeric reaction. In order to study the process quantitatively, acetone had to be chosen as a solvent, since the acid would be esterified by alcohol, and is only sparingly soluble in other media. The solutions were exposed in glass troughs to the rays from a quartz mercury lamp and protected from heat rays by a tank of running water, and as occasion required, filters of nitrosodimethylaniline in 0.0017% solution, and quinine sulphate in 0.05% solution were interposed to cut off the violet, blue and ultra violet light respectively. Preliminary experiments showed that the same results were obtained under the same conditions, that it was unnecessary to stir the solutions, and that the amount of transformation was practically proportional to the time of illumination. In order to study the influence of the intensity of the light, the lamp was stopped down so as to bring the source of light approximate to a point, and the solutions were placed at such distances that the intensities were in the ratio 4; 2; 1, and then illuminated for periods which varied as 1:2:4. It was found that slightly less transformation had occurred in the most remote vessel, thus showing that the Bunsen-Roscoe law, that the same quantity of light produces the same chemical effects, is not quite admissible. In further experiments on the influence of the initial concentration of the solution, the light was filtered through the quinine sulphate or nitrosodimethylaniline solutions, when, after allowing for the amount of light absorbed by these filters, it was found that the sum of the quantities of o-nitrosobenzoic acid formed was practically equal to the amount produced, under otherwise similar conditions, by unfiltered light. In the case of ultra violet light, the effect is independent of the concentration, but for violet light the speed of transformation is, at first, proportional to the concentration. The order of the reaction therefore changes with the kind of light, so that no simple law can be deduced to express the quantitative course of the reaction. No proportion existed either between the speed of the reaction and the amount of light absorbed by the aldehyde although they increased in the same direction. With mixed light, the chief work is done in dilute solutions by the ultra violet rays, and in concentrated solutions by the violet.

Oxalic Acid.

Various solutions of O.1N strength were exposed at 25° in a quartz flask to a Cooper-Hewitt quartz mercury vapor lamp at 10 cm. distance by *Mathews* and *Dewey* (J. Physikal. Chem., 1913, 17, 211). Under these conditions oxalic acid is very slightly affected but in the presence of uranium nitrate, sulphate or acetate is rapidly oxidized at a linear rate proportional to the uranium concentration. It is deduced that the decomposing action of ultra violet light is dependent on the amount of light photochemically absorbed.

Potassium permanganate and dichromate solutions are very stable towards ultra violet light, but the oxidation of sodium sulphite in contact with air is accelerated by these rays.

Lactic Acid.

According to *Euler* (Arkiv. Kem. Min. Geol., 1911, 4, No. 8, 1-10; J. Chem. Soc. 1912, Abs. 102, ii, 112) the degradation of lactic acid to carbon dioxide and alcohol takes place in pure aqueous solution under the influence of ultra violet radiations. The rate of decomposition of the lactic acid does not depend on the concentration of the acid within the limits studied, 0.25 N to N. The condensation of acetaldehyde to aldol also takes place without a catalyst on exposure to ultra violet light. The bearing of these results on the degradation and synthesis of plant acids is discussed.

Lactic and Tartaric Acids.

The decomposition of lactic and tartaric acids in ultra violet light has been investigated by *Euler* and *Ryd* (Biochem. Zeitsch., 1913, 51, 97-106; J. Chem.

Soc. 1913, Abs., 104, 544). Lactic acid in the presence of the short ultra violet rays undergoes a decomposition, analogous to a fermentation, with evolution of carbon dioxide. This reaction is less influenced by temperature than other photochemical reactions. The rate of evolution of carbon dioxide is not accelerated by the presence of either ferrous or ferric salts, but the latter are reduced. Tartaric acid undergoes similar changes in ultra violet light, with the formation of carbon dioxide and reducing substances. In this case ferric (not *ferrous*) salts increase the rate of gas evolution, being reduced themselves at the same time.

Synthesis of Carbohydrates.

In an investigation of the photochemical snythesis of carbohydrates from carbon dioxide and hydrogen in the absence of chlorophyll, *Stoklasa* and *Zdobnicky* (Biochem. Zeitsch. 1911, 30, 433; Monatsh., 1911, 32, 53) have found that water does not act on carbon dioxide in ultra violet light in the absence of potassium hydroxide, neither formaldehyde nor carbohydrate being formed in this case. If potassium hydroxide is added, however, formaldehyde, but no carbohydrate, is formed. The hydrogen must be in the nascent state for the reaction to take place, and ultra violet light must be present, otherwise formic acid is formed. A sugar is also formed when nascent hydrogen reacts with carbon dioxide in the presence of ultra violet rays. The nature of the carbohydrate has not yet been definitely established. The osazone melts at 196-200°, and is not, therefore, either B-formose or B-acrose.

The work of Stoklasa and Zdobnicky has been criticized by *Bob* (Biochem. Zeitsch. 1911, 31, 358).

Sugars.

Berthelot and *Gaudechon* (Compt. rend. 1912, 155, 1153) divide simple sugars into four classes according to their resistance to light; the keynotes are attached by ultra violet rays (λ 0.30μ), the aldoses by the rays ($\lambda=0.30$ to 0.25μ) the straight chain polyhydric alcohols by rays ($\lambda=0.25$ to 0.20μ) the ring polyhydric alcohols only by the extreme ultra violet rays($\lambda=0.20\mu$). With slow vibrations producing the first stage in the action, the liquid remains neutral, and does not reduce Fehling's solution in the cold. With more rapid vibrations, decomposition increases, the liquid becomes acid, and carbon dioxide can be detected in the gaseous products, the amount of hydrogen evolved increases and the solution begins to reduce Fehling's solution in the cold, and finally methane is liberated. The volumes of carbon monoxide and hydrogen evolved in the first stage always bear a simple ratio to one another. The results of a series of comparative experiments are given, and it is found in the case of the ketones that the solid sugars as well as their aqueous solutions undergo decomposition

Dextrose.

Euler and *Lindberg* (Biochem. Zeitsch., 1912, 39, 410; J. Chem. Soc. 1912, Abs. 102, ii., 407) find that an acid is formed from dextrose by the action of ultra violet light. On further action of the light the acid evolves a gaseous mixture containing 15% carbon dioxide, 40% carbon monoxide and 40% hydrogen. This gas is formed from the primary products of the action of light on the sugar. The scission of lactic acid in pure aqueous solution into alcohol and carbon dioxide which takes place in light is a special case of the evolution of carbon dioxide from vegetable acids. The condensation of acetaldehyde, a process so important in the formation of plant acids, is a light reaction. The rate of change of lactic acid into alcohol and carbon dioxide is, within certain limits, independent of theconcentration.

Dextrose and Galactose.

Variations in the photochemical decomposition of dextrose and galactose according to the wave-length of the radiations have been considered by *Berthelot* and *Gaudechon* (Compt. rend. 1912, 155, 831). Unlike the ketones, the aldoses, dextrose, galactose and mannose are practically unaffected on exposure in aqueous solutions to sunlight. They are, however, decomposed under the influence of medium ultra violet rays ($\lambda=0.30$ to 0.25μ). Carbon monoxide and hydrogen are evolved, and the corresponding alcohol, with one carbon atom less than the sugar used, is formed. As in the case of the ketones, secondary reactions occur when they are exposed to the extreme ultra violet rays, carbon dioxide and methane being evolved. The liquid becomes acid and capable of reducing Fehling's solution and ammoniacal silver nitrate.

Laevulose.

Under the influence of light from a quartz-mercury lamp, laevulose, according to *Bierry, Henri* and *Ranc* (Compt. rend. 1910, *151*, 316), undergoes profound decomposition when in aqueous solution, carbon monoxide, carbon dioxide, formaldehyde and methyl alcohol having been recognized among the products. The reaction proceeds more readily in a vacuum than when air is present. Aldoses do not appear to undergo this degradation. Glycerol and mannitol after exposure to the rays require reducing properties.

Berthelot and *Gaudechon* (Compt. rend., 1913, *156*, 707) use a 10 per cent. aqueous solution of laevulose to give a direct measure of the intensity of ultra violet radiation, the volume of the gas evolved being directly proportional to the time for any given radiation, and inversely proportional to the distance. Further, for dilute solutions (4.5 to 18 grams per litre) the velocity of the reaction is proportional to the concentration, while for strong solutions (720 to 1080 grams per litre) it is constant and independent of the concentration. These facts are best explained on the hypothesis that the velocity of reaction is proportional to the quantity of light absorbed per unit of time.

Sucrose.

Bierry, Henri and *Ranc* (Compt. rend., 1911, *152*, 1629) find the first action on sucrose of the light from a quartz-mercury lamp is to hydrolyse the sugar, and then to effect profound decomposition of the two hexoses, leading ultimately to the formation of formaldehyde and carbon monoxide.

A resumé of the published work on the inversion of sucrose by ultra violet rays and a reply to Bierry, Henri and Ranc is given by *Berthelot* and *Gaudechon* (Compt. rend. 1913, *156*, 468).

A study of the bioses, maltose, lactose, trehalose and gentiobiose, and the trioses, raffinose, melesitose and gentianose, by ultra violet rays of varying wave-lengths has been made by *Berthelot* and *Gaudechon* (Compt. rend. 1912, *155*, 1506). In the case of the trioses no first stage of formation of a monose and a biose could be detected. After the first stage of decomposition, the action was the same as in the case of the monoses.

Soluble Starch.

Massol finds that (Compt. rend., 1911, 152, 902) soluble starch becomes hydrolysed when its aqueous solution is exposed to the light from a quartz mercury lamp. Changes in the rotary power of the solution show that the transformation is probably into dextrins and maltose, although the amount of sugar isolated was insufficient for identification. The hydrolysis is not due to the small amount of hydrogen peroxide formed under the action of the rays.

Quinine Sulphate.

When an aqueous solution of quinine sulphate in contact with air is exposed to the light emitted by a quartz mercury vapor lamp, oxygen is absorbed. *Weigert* (Festschrift W. Nernst, 1912, 464; J. Chem. Soc. 1912, Abs. 102, ii, 1120) has made experiments directed to an explanation of the nature of this reaction. The progress of the change could be readily followed by measurements of the volume of gas absorbed.

The reaction velocity increases with increasing concentration of the quinine sulphate, but is diminished by addition of acid. From experiments with gas mixtures containing variable proportions of oxygen, it is found that the reaction velocity increases continuously as the partial pressure of the oxygen diminishes. For a mixture of oxygen and nitrogen containing 0.6 per cent. of oxygen, the velocity is about thirty times as large as for pure oxygen. The nature of the oxidation process appears to vary, however, with the proportion of oxygen in the gas mixture, for a larger proportion of the absorbed oxygen was found to have been activated when the gas mixture was rich in oxygen. The activated oxygen is only present to a small extent in the form of hydrogen peroxide, the major portion existing in a loosely combined form, which may be removed by a current of carbon dioxide or nitrogen

A similar influence of the oxygen concentration on the reaction velocity has also been observed in the photochemical oxidation of fluorescein and tetraiodofluorescein

Stereoisomerides.

In connection with the stereoisomerides of substituted ethylenes *Stoermer* (Ber., 1909, *42*, 4865; J. Chem. Soc. 1910, Abs. 98, ii, 114) states that the conversion of the labile into the stable modification by the action of light, particularly in the presence of a halogen, is not uncommon. The converse change, produced by light alone, has been remarked in very few cases. Perkin has noted the conversion of methylcoumarinic acid into methylcoumaric acid by sunlight, but Stoermer finds that in the coumaric acid series the tendency is the other way, the stable form changing to the labile under the influence of ultra violet light. Thus Perkin's change occurs only to the extent of 25 per cent., whereas coumaric acid yields 75 per cent. of coumarin, methylcoumaric acid yields 75 per cent. of methylcoumarinic acid, ethylcoumaric acid yields ethylcoumarinic acid quantitatively, and acetylcoumaric acid is also quantitatively changed to acetylcoumarinic acid. That the changes are caused by the ultra violet rays is proved by means of light filters, the interposition of a filter which absorbs ultra violet light between the lamp and the solution preventing any change of the stable to the labile modification. Hence the less fusible stable forms of stereoisomeric compounds can be changed directly, under definite conditions, into the more reactive labile modifications if energy is supplied by ultra violet light. Thus the stable form of o-anisylcinnamic acid, which could not be changed into the labile modification by Stoermer and Frederici has been converted to the extent of 50 per cent. by using a more intense light. In the case of stereoisomeric a-alkylated acids, the conversion of the stable into the labile form is a matter of great difficulty. The case of cinnamic acid is interesting. A benzene solution of ordinary cinnamic acid was exposed for eight days to the light of a Uviol lamp, with the result that 25-30 per cent. of Liebermann's isocinnamic acid, m.p. 58°, is produced. Allocinnamic acid in benzine is converted into ordinary cinnamic acid under similar conditions. Also fumaric acid changes to maleic acid in eight days, but the conversion of mesaconic acid into citraconic acid is very difficult, these being a-methylated acids. When stilbene in benzene is exposed to ultra violet light for eight days, it is converted to the extent of about 90 per cent. into isostilbene, which can be reconverted into stilbene by heating at 170-180° for one hour, by the vapor of fuming nitric acid in a few minutes, and quantitatively by exposure to sunlight of its solution in carbon disulphide containing a trace of bromine.

According to *Stoermer, Frederici, Brautigam* and *Neckel* (Ber. 1911, *44*, 637) the stable, less fusible forms of the following compounds are transformed into the labile or more fusible stereoisomerides when their benzene or alcoholic solutions are exposed to the action of the ultra violet rays from a uviol lamp for several days; coumaric acid, 75; methylcoumaric acid 75; ethylcoumaric acid over 90; propylcoumaric acid, 85; methylcoumaramide, 50; ethylcouramaramide 100, propylcouramaramide 95; methyl courmarate coumarin aceylcoumaric acid, over 90; methyl benzoylcoumarate; methyl oc-o-nitri-o-methoxycinnamate, 80; L-o-nitro-o methoxycoumaric acid, 40; p-methoxycinnamic acid, 25; sodium o-chlorocinnamate, 10; piperonylacrylic acid, 17; maleic acid; o-anisylcinnamic acid, 35-40; o-anisylcinnamide, 70; o-anisylcinnam-methylamide, 36, and the corresponding ethylamide, 40; B-o-anisyl-a-methylcinnamic acid, 5, and the corresponding amide, 5; cinnamic isocinnamic acid m.p. 42°, 30-40; phenyl tolyl ketoxime, 40; phenyl anisyl ketoxime. In most cases the reaction is a balanced one, and the number given for each compound represents the percentage for the less fusible compound which has been transformed when equilibrium is established. Crotonic acid is not transformed to any appreciable extent.

The method is recommended as a suitable one for the preparation of allo-stereoisomerides in several cases and also for the detection of spatial isomerism between a pair of compounds. In a few instances the addition of methyl or ethyl alcohol to the unsaturated compounds occurs during the exposure to the ultraviolet light, but the amounts of such products are usually small. It is suggested that the transformation and the percentage amount transformed depends on the energy differences between the steroisomerides. Sodium fumarate is not transformed, although the corresponding acid yields 30 per cent. of maleic acid. These investigators also state that o-chlorocinnamic acid, or its sodium salt, when exposed to ultra violet light is partly transformed into the allo-acid, $C_9H_7O_2Cl$, but when glacial acetic acid solutions are used, part of the acid combines with acetic acid, giving a product, $C_{11}H_{11}O_4Cl$, m.p. 212-213°. When a solution of mesaconic acid is subjected to the action of ultra violet light, water or methyl alcohol appears to combine with the acid.

Phenolphthalin.

Phenolphthalein is reduced to phenolphthalin by the action of nascent hydrogen. According to *Rossi* (Chem. Zentr. 1911, ii, 1659; from Giorn. Farm. Chim., 1911, 60, 433; J. Chem. Soc. 1912, Abs. *102*, ii, 107) while the reverse reaction takes place in the presence of hydrogen peroxide, and may be employed for the detection of blood. In the absence of the latter, the oxidation proceeds very slowly and may take days, but when blood is present the action is much more rapid. The test is carried out as follows: An alkaline solution of phenolphthalein is shaken with zinc dust until colorless, filtered, and the filtrate mixed with the solution to be tested, to which a few c.c. of 12 per cent. hydrogen peroxide have been added previously. If blood is present, a red coloration develops within three hours. Exposure to bright light, such as an arc-light, also increases the rapidity of the oxidation of phenolphthalin.

Santonin.

Piutti (Atti. R. Accad. Lincei, 1913, [v] 22, ii, 92-204; J. Chem. Soc. 1913, Abs, 104, ii, 896) states that carbon electrodes which have been alternately heated to redness and immersed in ferric choride solution a few times, or a carbon and an iron electrode, may be employed with advantage instead of iron electrodes for the arc used as a source of light in certain ultra violet light experiments. The curves obtained indicate that the transformation of santonin into photosantonic acid and isophotosantonic acid by light proceeds by way of intermediate compounds. Photosantonic acid and probably also isophotosantonic acid. are very transparent to the ultra violet rays, but santonin is not. No confirmation could be obtained of the alleged re-conversion of yellow santonin into white on boiling. The alleged visible alteration of santonin crystals under the action of light could not be observed. Asparagine, lactic acid, and carbamide are said to be almost completely transparent to the light of the iron arc.

Phototropy of Fulgides and Other Compounds.

Fulgides, containing aromatic substituting groups are reported by *Stobbe* (Annalen, 1908, 359, 1, J. Chem. Soc. 1908, Abs. 94, ii., 339) to undergo change in color when exposed to light. Thus triphenylfulgide, which forms pleochroic, orange-red, monocline crystals, becomes dark brown when exposed to sunlight or the rays of an arc lamp, changing again to its original color in the dark. The brown and orange modifications are chemically identical, and differ only in the solid state. Such phenomena have been termed by Marckwald (Zeit. physikal. Chem. 1899, 30. 140) phototropy. If this phototropic change is frequently repeated, the difference between the shades of the two forms becomes gradually less, a chemical change taking place which leads finally to the complete conversion of the fulgide into a new substance, the photoanhydride. To study the action of light waves of different lengths, the fulgide is exposed in a thin layer between two glass plates in a special spectrographic apparatus. Orange-yellow triphenyfulgide, when exposed to the light of the spectrum, after two minutes shows a broad band between the spectrum lines E and G, which after prolonged exposure gradually extends towards the ultra violet. The yellow modification is sensitive to blue and violet light rays, but a blackish-brown form which is intermediate between the yellow and brown modification is sensitive to yellow and red rays. The portion of the spectrum which causes the phototropic change from the yellow into the brown modifications is termed the zone of stimulation. The behavior of a number of di- and tri-arylfulgides towards the light rays of different wave-lengths has been studied in this manner. Phototropic change has been observed only with the lemon-yellow to orange-red diaryl—and the orange-red to dark red triarylfulgides; the colorless alphyl, greenish-yellow to yellow monoaryl, and red, purple-red, or brown or tetra-arylfulgides are not phototropic.

The modifications of a phototropic substance can exist in the pure state only when exposed to light rays of the wave-length under the influence of which they are formed. Under all other conditions, the substance is a mixture or solid of the one form in the other. The phototropic change is caused by the light rays which are absorbed by the modification undergoing the change. Hence the brown form of triphenylfulgide must be in reality blue, the brown appearance resulting from its state of granulation. The equilibrium between the two modifications in a mixture depends on the wave-lengths of the light to which it is exposed. It follows that the parts of the spectrum which produce the phototropic change depend on the colour of the fulgide, the zone of stimulation lying the more towards the violet the deeper the normal shade of the substance, and that the amount of change in the colour of a phototropic fulgide not only increases with diminishing wave-lengths of the light rays and with increasing intensity of illumination, but diminishes with increasing temperature and depends, further, on the number and nature of the substituting groups, being greatest with diphenyl-o-methoxyphenyl-diphenyl-piperonylallo-, and diphenyl-o-nitrophenylfulgides, less with diphenyl-o-methoxyphenylfulgide, and least with the diarylfulgides. The furyl-fulgides resemble the phenyl compounds.

The phototropy of other substances has been studied in a similar manner. The zone of stimulation for colorless B-tetrachloro-æ-ketonaphthalene lies in the ultra violet, whilst the reverse change is caused by yellowish-green or yellowish rays. Red and blue rays have no action.

Phenylbenzylidenehydrazine, which forms light yellow crystals or a white powder, becomes red on exposure to violet or ultra violet rays, becoming again colorless when exposed to yellow or green light. Phenylanisylidene- and phenylcuminylidene- hydrazines behave in the same manner, as do also osazones of the benzil series (Biltz and Wienands, Abs., 1899, i, 910). Tetraphenyldihydrotriazine (Walther, Abstr., 1903, i, 592) and ethyl oxalisobutyrate (Wislicenus and Kiesewetter, Abstr., 1898, i, 240) have also been observed to exhibit phototropy.

Nature of Bleaching.

When a system sensitive to light absorbs light very strongly and becomes bleached as a result of the chemical change, thus allowing the light to act on deeper layers, it should be possible according to *Plotnikoff* (Zeitsch. physikal. Chem. 1911, 78, 293; J. Chem. Soc. 1912, Abs. 102, ii, 4) to follow the rate of the reaction from the rate of bleaching of the solution. This is realized in the combination of bromine with cinnamic acid in benzene solution. A glass tube was filled with the solution, and the end closed with a glass plate placed horizontally, and light from a uviol lamp allowed to enter from the end through the glass cover, access of light to the sides and the other end being carefully guarded against In these circumstances bleaching proceeds gradually from the illuminated end until the solution is completely decolorised.

Cause of Bleaching of Dyes.

Gebhard (Zeitsch, angew. Chem. 1910, *23*, 820; J. Chem. Soc. 1910, Abs. 98, ii, 405) has confirmed the theory (Zeitsch. angew. Chem. 1910, *22*, 2484) that the bleaching of dye solutions or of dyed tissues by light is due to the primary formation of a peroxide of the dye. The peroxide is best detected by acidified potassium iodide and starch, by alkaline potassium permanganate, or by diphenylamine and concentrated sulphuric acid. Chromic, molybdic and titanic acids do not indicate the presence of a peroxide, which fact furnishes one of Gebhard's several arguments against the theory of the primary formation of hydrogen peroxide. The rays which are most effective in the production of the peroxide are those complementary to the color of the dye. Blue, violet and ultra violet rays exert a decomposing action on the peroxide, or occasion a transference of the active oxygen to unattacked molecules of the dye. Gebhard utilises Mumm's theory of oxidation in the presence of water and shows by an electrolytic experiment that the perhydroxyions are instrumental in bleaching the dye.

Dye Solutions.

In liquids exposed to the action of light, condensation nuclei are formed. These bring about local increases in concentration and accelerate chemical reactions which do not take place in the dark. According to *Weigert* (Ber. 1910, *43*, 164) proof of the formation of condensation nuclei is afforded by the fact that solutions of dyes exposed to light show an increased solvent action towards gases.

The dyes studied were uranin, erthrosin-G and -J, phloxin, methyl-violet and malachite-green. These were enclosed in tubes with nitrogen, maintained at 15°, and exposed to the light from a mercury lamp. A manometer was arranged to indicate the gas pressure in the tubes, which were constantly shaken. The solubility of nitrogen in water is not affected by exposure to light. In the dye solution a decrease in pressure took place, at first with constant velocity, but subsequently becoming slower. After keeping the tubes in the dark again, an increase in pressure was found, but the original value was never attained. A special differential-absorptiometer was designed to remove the absorbed. The amount of dye present in solution is far was found possible to recover only a portion of the gas absorbed. The amount ofdye present in solution is far too small to explain the increased solubility of the gas as due to the influence of the dyes. Undoubtedly, condensation nuclei form, and the nitrogen condenses at their surface.

Chlorophyll.

Alcoholic solutions of chlorophyll (from spinach) in quartz vessels were exposed by *Bierry* and *Larguier des Bancels* (Compt. rend., 1911, 153, 124-125; J. Chem. Soc., 1911, Abs., *100*, 735), to the light of two mercury vapor lamps for twenty-four to forty-eight hours. The solutions became faintly yellow and no longer showed the absorption bands characteristic of chlorophyll. Tests for urobilinogen were applied, with positive results. A benzene solution of chlorophyll became colorless under the same conditions, but did not show the color reactions of unrobilinogen.

It has been previously shown that only the rays actually absorbed are causative of the decolorization of chlorophyll. According to *Dangeard* (Compt. rend., 1913, 156, 1844) when light is allowed to act on a mixture of chlorophyll and pinaverdol, the latter is first decolorised at its own absorption band, from which it follows that the latter is attacked and finally destroyed through the energy absorbed by the chlorophyll, and not by that absorbed itself. The experiments have been extended to a variety of colored substances, with the general result that radiations which are completely inactive towards a pure substance are found to become active in the presence of a second pigment. Since chlorophyll in the plant is accompanied by various yellow pigments, such as carotine and xanthopyll, and decolorization is complete at the bands I, II, III and IV, it follows that these pigments are also attacked and ultimately decomposed through the energy absorbed by the chlorophyll.

Selective Destruction of Enzymes.

Malt amylase is found by *Chauchard* and *Mazour* (Compt. rend., 1911, *152*, 1709) to be much more sensitive to ultra violet light than the invertase from yeast. It is therefore possible by exposing a mixture of the two to the light from a quartz-mercury lamp to destroy the activity of one before that of the other.

Resins.

From the results of a series of preliminary investigations *Vignolo-Lutati* (Atti. R. Accad. Sci. Torino, 1912, *47*, 841; J. Chem. Soc. 1912, Abs. 102 ii, 882) draws the conclusion that the photochemical action of resins is both chemical and physico-chemical in character. Either the formation of ozone or peroxide during the auto-oxidation of resins, or some other modification in their chemical equilibrium, is apparently accompanied by the emission of rays of very short wave-length, to which the photochemical efforts are due.

Colored Resinates.

The solubility of colored resinates submitted to the action of light has been investigated by *Larguier des Bancels* (Comp. rend., 1912, 155, 280; J. Chem. Soc. 1812, Abs. 102, ii, 882). Colored resinates are prepared by treating resin with aqueous solutions of alkali hydroxides, adding a suitable coloring matter (safranine, rhodamine, etc.), and then precipitating with a salt of zinc or magnesium. These substances when dissolved in terebene, spread in a thin layer on glass plates, dried, and exposed to the light of the sun or of a mercury vapor lamp, became, at the end of a certain time, insoluble in such solvents as benzene, but soluble in solvents such as methyl or ethyl alcohol. This effect on the solubility is produced essentially by radiations of short wave-length and also depends on the drying, since, if this is pushed too far, the non-illuminated resinates dissolve in alcohol.

Fehling's Solution.

According to Byk, Fehling's solution is decomposed by light of wave-lengths less than 400 $\mu\mu$, corresponding with an absorption band in the ultra violet, whereas the red and yellow waves of the visible absorption bands have no action. This is contrary to the rule that radiations which are absorbed by a substance tend to destroy it.

It is suggested that the red light absorbed by Fehling's solution is not active enough to produce a decomposition unaided, whereas in presence of a suitable reducing agent its activity might be sufficiently reinforced for it to do so.

In accordance with this suggestion *Leighton* (J. Physikal. Chem. 1913, *17*, 205; J. Chem. Soc. 1913, Abs. 104, ii, 459) finds that in presence of quinol within certain very narrow limits of concentration Fehling's solution is reduced by red light, but is stable in the dark.

Ozone.

When a tube of fused quartz was exhausted until the pressure registered only a few millimeters and charged from an induction coil, *Goldstein* (Ber., 1903, 36, 3042) observed an intense odor of ozone in the surrounding atmosphere, and iodized starch paper was turned blue quickly. The odor of ozone was not perceptible when the pressure inside the tube exceeded a certain value; it was perceptible at very small pressures, and was not intense when the light from the discharge was at its brightest. The phenomenon is ascribed to the ultra violet light rays of small wave-length penetrating the quartz and then converting the atmospheric oxygen into ozone. A Geissler tube was exhausted and oxygen was passed into it until the pressure registered several centimeters. The tube was then partially immersed in liquid air and charged from an induction tube. After ½ min., the tube became luminous until the pressure was several centimeters and the sparking continued. By repeated treatment in this manner, oxygen can be entirely converted into ozone, which was obtained as a dark blue liquid. The spectrum of pure oxygen may readily be investigated by the aid of this method, since organic substances present are attacked by the ozone, even at the temperature of liquid air. Goldstein notes that Lenard (Drudes Ann. d. Physik. 1, 486, 1900) had observed that ozone was formed by the action on air of sparks from a Leyden jar. The formation of ozone in greatly rarefied air by the method employed by Goldstein was first reported by the latter.

Bordier and Nogier (Compt. rend., 1908, 147, 354) could not find that ozone was produced from the oxygen of the air by action of ultra violet light, although others had observed its formation. Using a quartz mercury lamp as the source of ultra violet light, *Aubel* (Compt. rend., 1909, 149, 983; 1910, 150,

96) definitely proved that ozone is produced. Instead of using water to absorb the ozone, olive oil and light petroleum were employed in the first experiments, being placed in porcelain dishes inside a large glass globe surrounding the quartz tube. After several hours' exposure starch iodide showed the presence of ozone in these liquids. When distilled water was submitted to the action of the ultra violet light for fourteen hours, the presence of ozone was detected by its action on a photographic plate. Starch iodide paper was turned blue in two minutes, except where it was covered with a piece of quartz, and thus prevented from coming into direct contact with the ozonized air. In the experiments where water was used to absorb the ozone produced, the resulting solution contains hydrogen peroxide, the presence of which was detected by its action on the photographic plate. The presence of hydrogen peroxide in the water is claimed to prove the formation of ozone in the air by the action of the ultra violet light.

Bahr (Ann. Physik. 1910, (iv), 33, 598; J. Chem. Soc. Abs. 1910, 98, ii, 949) exposed ozonized oxygen to ultra violet light from a quartz-mercury lamp and measured the rate at which the ozone was decomposed. The rate of decomposition increases rapidly as the pressure on the gas is reduced. For a given intensity of the incident ultra violet radiation, the ozone disappears at a rate which agrees with the requirements of the equation for a unimolecular change, if the pressure is kept constant. In consequence of the decomposing action of ultra violet light, the measurement of the absorption of ultra violet radiation cannot be applied to the estimation of ozone at low temperatures.

Weigert (Zeitsch. Elektrochem. 1912, 18, 654) also describes a method by which the sensitiveness of the reaction of decomposition of ozone in ultra violet light can be compared with that in visible light. The sensitiveness, as measured by the amount of decomposition under conditions otherwise comparable, is 2.3×10^8 mol. per cal. in ultra violet light, and 4.8×10^{10} mol. per cal. in ordinary light in the presence of chlorine as sensitiser.

Weigert (Ber., 1913, 46, 815) has stated that in order to investigate the photochemical reaction of ozone with hydrogen it is necessary to use that part of the spectrum where ozonization of oxygen does not occur. This he attained by using a quartz-mercury lamp, and allowing the rays to pass through a layer of air before entering the reaction vessel. No trace of hydrogen peroxide was formed and there was only an extremely slow reaction in the dark. In ultra violet light, however, about one-third of the ozone originally present disappeared in two minutes, the disappearance being due to the two reactions: $2O_3 = 3O_2$ and $H_2 + O_3 = H_2O + O_3$. The total amount of ozone decomposed is proportional to the ozone concentration.

The results indicate that in the activation of oxygen by ultra violet rays two photochemical reactions occur. In the formation of water from hydrogen and oxygen, the oxygen is first ozonized by the short rays, and then reacts with hydrogen under the influence of the long rays. In the photochemical dissociation of water vapor a further photochemical reaction plays a part, namely,

$$H_2O = H_2 + O,$$

which is effected by the short rays.

It is possible that the deviation of the nitric oxide equilibrium from the position calculated thermochemically is due to the photochemical action between nitrogen and ozone, the latter being formed from oxygen by the ultra violet rays.

A further study of these reactions by *Weigert* and *Bohm* (Zeitsch. physikal. Chem. 1915, 90, 189) on mixtures of ozone and dry hydrogen, containing from 2.4% to 92.5% hydrogen, using a quartz-mercury lamp operating at 6 amperes and 65 volts, has furnished additional details. The gas was passed in a stream along a tube which was of such dimensions that it contained sufficient ozone to absorb completely the whole of the photochemically active light light, particularly that with wave-length about $258\mu\mu$. By means of these experiments the catalytic influence of ultra violet rays on the simultaneous ozone decomposition and water formation in the mixtures was carefully studied. By measuring the volume change occasioned by illumination, and by analysis of the gas mixture before and after illumination, it was shown to be possible to determine the extent to which both changes had taken place. It is shown that when the gaseous mixture is kept in the dark no reaction of any kind takes place between ozone and hydrogen. On illumination, the two reactions (I), $2O_3 = 3O_2$ and (II), $H_2 + O_3 = H_2O + O_2$ occur, as stated above, and further, the reaction (III), $2O_3 + H_2 = H_2O_2 + 2O_2$, cannot be observed under the experimental conditions. A consideration of the volume changes which occur on illumination show that with a large excess of hydrogen the reaction takes place mainly according to equation (II), but with larger quantities of ozone equation (I) represents the major portion of the reaction. Equation (I) is accompanied by an increase in volume, whereas equation (II) is accompanied by a decrease. At the point where there is neither contraction nor increase in volume, it is shown that of three molecules of ozone reacting, two react according to equation (I) and one according to equation (II). The photochemical decomposition of ozone in the absence of hydrogen is a relatively slow process, but it is strongly accelerated by even small quantities of hydrogen. With a small quantity of hydrogen, the velocity of decomposition of ozone is proportional to the ozone concentration, and from 8% hydrogen upwards it is independent of the hydrogen concentration. With a large excess of hydrogen the order of the reaction is greater than unity, but with larger ozone concentrations it is less than unity. From this it is shown that the effect of two simultaneously occurring photochemical reactions cannot be regarded as the sum of the two single effects. The photochemical water formation is proportional to the ozone concentration for low concentrations of ozone, but at higher concentrations it approaches a limiting value, which lies higher, the higher the partial pressure of the hydrogen. With a constant ozone concentration the water formation is approximately proportional to the hydrogen concentration. With an excess of hydrogen of about one hundred times the quantity required for the formation of water according to equation (II), the reaction proceeds practically entirely according to this equation.

Jobling (Martin's Industrial Gases, New York, 1916, 134) gives Lenard the credit of the discovery that air or oxygen is "activated" by ultra violet light and calls attention to a photochemical method of making ozone proposed by Potter (U. S. Patent 845,965) involving the construction of an ozonizer in which a quartz-mercury vapor lamp is surrounded by a sheathing of ordinary glass, between which and the quartz wall of the lamp, air is spirally conducted. For industrial purposes, Jobling states the only practical method of producing ozone is that of passing dry air through a chamber where it can be subjected to the influence of a silent high-tension electric discharge. It is not certain whether the production of ozone by silent discharge is fundamentally an electrolytic phenomenon, dependent upon the electric stress developed, or whether it is to be attributed to the ultra violet rays developed. The latter is the more probable. (Harries).

Origin of Atmospheric Ozone.

From a series of experiments on the origin of atmospheric ozone *Henriet* and *Bonyssy* (Compt. rend., 1908, 146, 977; J. Chem. Soc. 1908, Abs. 94, ii, 578) conclude that ozone is formed at the expense of the oxygen of the high regions of the atmosphere under the influence of the ultra violet rays of the sun and is carried to the lower layers of the air by winds and rain. The proportion of ozone in the air is at a maximum during a West or Southwest wind and at a minimum during an East wind, and it is also increased during clear, calm weather by the direct action of the solar radiations on the lower layers of air.

Ozone and Chlorine.

The decomposition of ozone by light in presence of chlorine has been studied quantitatively by *Weigert* (Zeitsch. Electrochem., 1908, 14, 591), the light of a mercury quartz lamp being used, and the rate of decomposition being measured by means of the change of pressure of the gas. There is no induction period, and decomposition stops when the gas is cut off. The rate of decomposition is independent of the concentration of the chlorine, but not in proportion to it, and it is nearly proportional to the intensity of the light. By placing a vessel containing chlorine between the source of light and the ozone tube, a measurement of the quantity of light absorbed by the chlorine is obtained; in this way it is shown that the rate of decomposition of the ozone is proportional to the quantity of light absorbed by the chlorine mixed with it. A rise of temperature of 10° increases the rate of reaction 1.17 times. It is suggested that the light produces some intermediate product which is destroyed rapidly by the action of ozone; the rate of decomposition measured is then the rate of formation of this product, which is independent of the concentration of the ozone.

Formation of Water.

Under the action of ultra violet light at 150°, hydrogen and oxygen combine almost completely, with the formation of water vapor. Although combination takes place with considerable velocity, there is no explosion. At the same temperature, water vapor is decomposed by ultra violet light to a very small extent, the minimum decomposition found to be 0.00087-0.0010%. This amount of decomposition is the same as the thermal decomposition existing at about 1,250°, so that the equilibrium under the influence of ultra violet light is different from the ordinary thermal equilibrium (Coehn, Ber., 1910, 43, 880).

After discussing recent work on the chemical effects of ultra violet light, *Andrèeff* (J. Russ. Phys. Chem. Soc., 1911, 43, 1342; J. Chem. Soc. 1912, Abs. 102, ii, 112) describes his own experiments which have been carried out with a mercury lamp at various voltages and currents.

With a voltage of 220, hydrogen and oxygen combine to form water with moderate rapidity. The velocity of the reaction, which terminates in from five to twenty hours, is independent of the concentrations of the reacting substances, and is in good agreement with the expression $dx/dt = C$; it increases almost proportionately with the intensity of the light. The mean value of the temperature-coefficient of the reaction is 1.1.

Water also decomposes under the influence of ultra violet light, in the field of action of which an equilibrium is established between hydrogen, oxygen and water, this equilibrium differing from the thermal equilibrium at the corresponding temperature. When the initial product is a mixture of hydrogen (2 vols.) and oxygen (1 vol.) the final position of equilibrium is the same as when water is employed. With increase of the intensity of the ultra violet light, the equilibrium is displaced in the direction of the dissociation, and the percentage of water decomposed increases proportionately with the increase of intensity.

Photo-Electric Properties of Water.

Experiments are described by *Obolensky* (Ann. Physik, 1912, (iv) 39, 961; J. Chem. Soc. 1913, Abs., 104, ii, 3) which show that water is photo-electrically sensitive to ultra violet rays of very short wave-length. The ultra violet light was obtained from the spark discharge between aluminum electrodes, and by the interposition of screens of fluorspar quartz, air, calcspar, glass and gypsum, it was possible to eliminate portions of the ultra violet spectrum in a series of stages. In this way it has been found that the most active rays are those of the extreme ultra violet region in the neighborhood of $\lambda = 130\ \mu\mu$. For this group of rays, the photo-electric activity of water is about 1/400th of that cupric oxide. As the wave-length increases, the exciting power of the rays falls off very quickly, and vanishes completely when exceeds 202.5 $\mu\mu$.

The addition of small quantities of acids, bases and salts has no apreciable influence on the photo-electric activity of water. In larger quantities, chlorides diminish the effect, while sulphates, carbonates and nitrates increase it. The presence of the dissolved salts also causes a displacement of the spectral position of the rays which exert the maximum effect. Ice is more photo-electrically sensitive than water. For the unfiltered rays from the aluminum spark discharge, its activity is about 0.7 of that of cupric oxide, and for the group of rays in the neighborhood of $\lambda = 180\,\mu\mu$, it surpasses cupric oxide in its sensitiveness. Experiments with hoar-frost show that this behaves very similarly to ice. The meterological significance of the observations is referred to.

Hydrogen Peroxide.

Henri and *Wurmser* (Compt. rend., 1913, 157, 126) have made a study of the photochemical decomposition of hydrogen peroxide by monochromatic light from the ultra violet portion of the spectrum. The results confirm those of Tian for total light, that the reaction is unimolecular, and that the velocity of decomposition is proportional to the concentration. For each wave-length the velocity is proportional to the incident energy. It is further proportion to the absorbed energy, the factor being constant for wave-lengths between 2,800 and 2,050, the photochemical susceptability varying proportionately with the absorption.

Henri and *Wurmser* (Compt. Rend., 1913, 157, 284) further state that the addition of traces of numerous different substances to hydrogen peroxide renders it stable towards ultra violet rays, alkalies being more active than acids in this respect. Henri and Wurmser suggest that in many of the cases of catalysis by ferments and colloidal metals, the action of poisons is on the substances undergoing transformation, and not on the catalyst itself. Further, that the action of certain ferments is quite comparable to that of the ultra violet rays. *(To be continued in the July issue.)*

U. S. Tariff Commission Completes Coal-Tar Products Census

The United States Tariff Commission announces the completion of its census of coal-tar products for 1917. This group of products include, not only the coal-tar dyes and the crude and intermediate materials required for their manufacture, but also all the medicinal and photographic chemicals, explosives, synthetic resins, synthetic perfume materials, and flavors which are in any way derived from coal-tar products. There were produced in the United States (not inclusive of explosives and synthetic phenolic resins) 54,367,994 pounds of dyes and other finished products, which have a total value of $68,711,228. The production of the materials known as intermediates amounted to just 322,650,531 pounds, with a value of $106,942,918.

The annual production was reported for the following groups of products made in whole or in part from materials derived from coal tar: 45,977,246 pounds of dyes valued at $57,796,027; 5,092,558 pounds of color lakes valued at $2,764,064; 2,236,161 pounds of medicinal chemicals valued at $5,560,237; 779,416 pounds of flavors valued at $1,862,456; 263,068 pounds of photographic chemicals valued at $602,281, and 19,545 pounds of perfume materials valued at $125,960.

There were 81 establishments engaged in the manufacture of coal-tar dyes in 1917 and their production during that year was practically identical with the amounts annually imported before the war. The imports of the fiscal year 1914 amounted to 45,840,866 pounds and the production in the United States in 1917 was 45,977,246 pounds. However, an analysis of this total reveals that the domestic production, though equal in quantity to the preceding imports, differs in the relative amounts of the various classes of dyes. Only a small production was reported for indigo, and the alizarin and vat dyes derived from anthracene and carbazol,—classes of dyes which include some of the best and fastest colors known to the textile trade. The United States produced only 2,166,887 pounds of these dyes in 1917; and the elimination of 1,876,787 pounds of extract made from imported indigo, reduces the output of these dyes to less than three per cent. of the pre-war imports. Dyes of this class are dutiable at 30 per cent. in the Tariff Act of 1916. The lack of development in the manufacture of these particular dyes promises to be remedied to a considerable extent in 1918, for a number of firms have begun their manufacture and a large increase in production can clearly be foreseen.

In the classes of dyes which if imported would be dutiable at 30 per cent. plus five cents a pound, the American manufacturers have shown remarkable progress, producing 43,810,359 pounds at a total value of $57,639,990. That this represents something of an excess over the American needs is evidenced by the fact that during the fiscal year 1917, American-made dyes to the value of $11,509,287 were exported to other countries. Thus the exports exceeded the pre-war imports in total value, although not in tonnage nor in the variety of the dyes.

The development of the manufacture of intermediates is equally marked, for before the war almost all of these necessary materials were imported from Germany. The Tariff Commission finds that intermediates were manufactured by 117 firms in 1917 and that the production amounted to 322,650,531 pounds valued at $106,942,918. These figures, however, are somewhat misleading, as there is inevitable duplication in the totals. It is well known that many of the intermediates are derived from other products of the same class. Thus starting with benzol the following succession of products is obtained: nitrobenzol, anilin,

(Concluded on page 274.)

NEW PUBLICATIONS

Protecting the Eyes from Injurious Radiations

The new publication of the U. S. Bureau of Standards (Technologic Paper No. 93) entitled "Glasses for Protecting the Eyes from Injurious Radiations" is the second and an enlarged edition of this work, which was prepared by W.W . Coblentz and W. B. Emerson, of the Bureau.

It contains considerable new data on the spectral transmission of glasses suitable for protecting the eyes from injurious rays, e. g., euphos, fieuzal, akopos, and noviweld glasses. An appendix is added which gives the transmission of the radiations from a gas-filled tungsten lamp; a magnetite arc, and a quartz mercury vapor lamp through various glasses, thus showing in a condensed table the protective properties afforded by these glasses. This paper is now ready for distribution and those interested may obtain a copy by addressing a request to the Bureau.

Report on Technology of Salt Making

The rumor that the United States some time ago was threatened with a famine in salt was baseless, according to a report on the technology of salt making in the United States, recently issued by the Bureau of Mines, Department of the Interior. W. C. Phalen, mineral technologist, the author of the bulletin, reviews the industry and draws certain conclusions from visits to the operating plants in the United States. One of these conclusions is that there is an excess of plant capacity as compared with domestic requirements.

Mr. Phalen says:—"The consensus of opinion seemed to be that much more salt was being produced than could be marketed, estimates of over production ranging from 25 to 50 per cent. The facts that large up-to-date plants were not working at full capacity, that others were working at half time or half capacity, and that others were either temporarily or permantly closed are significant to those planning to enter the salt business. These statements, of course, apply to the normal conditions which obtained before the war.

"The keenness of competition in the salt industry prevents tying up large stocks and cornering the market which is further prevented by the great abundance of this natural commodity, its widespread distribution and the fact that its production is not restricted to a few manufacurers, but is in the hands of many independent producers. It follows, therefore, that a scarcity of salt in any part of the United States is due, not to a possible shortage of the original supply of salt itself, but to other factors entering into the salt industry, such as shortage of labor, fuel and difficulties in transportation.

"The imporance of the industry needs no comment. The domestic output in the United States in 1916 was nearly 6,400,000 short tons, and it is estimated that in 1917, it will be nearly 6,950,000 short tons. The industry is scattered over fourteen states, distributed from coast to coast and from the Great Lakes to the Gulf. The low value of the commodity has prevented its transportation to considerable distances, except where local prejudice has favored a certain brand. This competition has lead to loss.

"The United States has produced in recent years very nearly all the salt it has consumed. The small importations, usually not more than two or three per cent. of the total consumption, have come to the Atlantic seaboard. This illustrates how, in the case of a low-priced and abundant commodity, freight rates regulate distribution and competition, not only among domestic producers, but from foreign sources as well.

"The rapid deterioration of equipment is another item in the salt business which has received consideration in the report. The wear and tear on all salt-making machinery is heavy. If a plant is allowed to remain idle for any considerable length of time, it is well-nigh ruined. For this reason it may often be cheaper to make salt for a season without profit than to shut down. In figuring costs and basing selling prices on them, some producers have not provided for the rapid deterioration of plant, and this, together with over production, has caused losses among salt manufacturers during the past decade."

Portland Cement with High Magnesia Content

A new publication has been issued by the U. S. Bureau of Standards (Technologic Paper No. 102) entitled "The Properties of Portland Cement Having a High Magnesia Content."

A series of cements was burned in the Bureau's experimental rotary kiln in which the limestone used in the raw material was replaced in part or in whole by dolomite. A magnesia content as high as 25 per cent. was obtained in the resulting cement and the clinker was examined petrographically. The constituents present, their amount, and the character of their formation were carefully studied. The clinker was also ground and the resulting cement subjected to the usual tests for physical properties. The results show that cements not exceeding 8 per cent. in magnesia content will produce concretes of satisfactory strength at the end of 1½ years. With this amount of magnesia, monticellite and spinel (constituents not present in cements of lower magnesia content) appear; and these cements seem to hydrate with a large increase in volume. The publication is a part of the program of the systematic investigations on the technology of Portland cement.

This paper is ready for distribution and those interested may obtain a copy by addressing a request to the Bureau.

New Publications of the U. S. Bureau of Mines

(List 58.—May, 1918.)

BULLETINS.

Bulletin 110. Concentration experiments on the siliceous red hematites of the Birmingham District, Ala., by J. T. Singewald, Jr. 1917. 81 pp., 1 pl., 47 figs.

Bulletin 132. Siliceous dust in relation to pulmonary disease among miners in the Joplin District, Mo., by Edwin Higgins, A. J. Lanza, F. B. Laney, and G. S. Rice. 1917. 115 pp., 6 pls., 6 figs.

Bulletin 146. Technology of salt making in the United States, by W. C. Phalen. 1917. 149 pp., 24 pls., 10 figs.

TECHNICAL PAPERS.

Technical Paper 148. The determination of moisture in coke, by A. C. Fieldner and W. A. Selvig. 1917. 14 pp.

Technical Paper 182. Flotation of chalcopyrite in chalcopyrite-pyrrhotite ores of Southern Oregon, by Will H. Coghill. 1918. 13 pp., 1 fig.

Technical Paper 183. New views of the combustion of the volatile matter in coal, by S. H. Katz. 1918. 15 pp., 1 fig.

Technical Paper 201. Accidents at metallurgical works in the United States during the calendar year 1916, by Albert H. Fay. 1918. 18 pp.

NOTE.—Only a limited supply of these publications is available for free distribution, and applicants are asked to co-operate in insuring an equitable distribution by selecting publications that are of especial interest. Requests for all papers can not be granted. Publications should be ordered by number and title. Applications should be addressed to the Director of the Bureau of Mines, Washington, D. C.

Dimethylaniline and Diphenylamine

(Concluded from page 260.)

Diphenylamine is used in color making for the preparation of Orange IV, Diphenylamine Blue, certain sulphur blues, and other colors.

It is especially employed at present to lend stability to high explosives.

Its hexanitrated derivative is a more powerful explosive than picric acid, and merits the attention of the artillery authorities. It is not prepared by direct nitration of diphenylamine but by preparing to begin with asymetric dinitrodiphenylamine, which is obtained by condensing the dinitrochlorobenzene, 1 : 2 : 4, with anilme, then nitrating this as far as the process can be carried.

By methylation diphenylamine gives methyl-diphenylamine, which has found a limited employment in color making. This is prepared by heating in an autoclave a mixture of 100 kilos of diphenylamine, 68 kilos of hydrochloric acid, and 24 kilos of methyl alcohol for ten hours at 250° to 300° C., and at a pressure of 10 to 15 kilos per square centimetre.

Technical Men Unite

(Concluded from page 262)

Illinois Society of Engineers.

Illinois Society of Architects.

The American Railway Engineering Association.

The Swedish Engineers' Society of Chicago.

Illinois Chapter, American Institute of Architects.

Chicago Section, American Society of Refrigerating Engineers.

Chicago Section, Steel Treating Research Society.

Chicago Section, Illuminating Engineering Society..

Chicago Chapter, American Association of Engineers.

Officers of the War Committee have been elected as follows:

Chairman—F. K. Copeland.

Vice-Chairman—W. L. Abbott.

Secretary—Edgar S. Nethercut.

Treasurer—William A. Fox.

The executive committee consists of F. K. Copeland, W. L. Abbott, William Hoskins C. A. Keller, Charles E. Lord, C. F. Loweth, Isham Randolph and Richard E. Schmidt. The address of the Secretary of the War Committee is 1735 Monadnock Block, Chicago.

New Electric Furnace

(Concluded from page 254)

tion of the zinc. The electric furnace is closed and these losses are avoided. It is estimated that the unnecessary losses in brass-making are more than $3,000,000 a year in normal times and perhaps $10,000,000 a year in war times. Another claim for the electric furnace is that it gives more healthful working conditions for the men.

The Michigan Smelting and Refining Co., Detroit, Mich., already has one of these furnaces in operation and has four more under construction. The C. B. Bohn Foundry Company of Detroit is building two of these furnaces.

Coal-Tar Census Completed

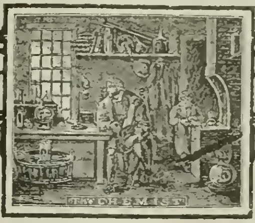
(Concluded from page 272.)

acetanilid, nitroacetanilid and nitranilin. Each of these products had to be reported by the manufacturer and hence there has been some cumulative counting.

The totals for all of the coal-tar products will be published in the final report.

CHEMICAL INVESTIGATION
EFFICIENCY & CONTROL

CONDUCTED BY CHARLES B. DAVIS, F.C.S.



ALL classes of work covered by the following subjects will be done for readers of "The Chemical Engineer" through this department by Mr. Davis: Special research of every description; analysis and reproduction of any commercial product; prevention of waste and utilization of by-products on the most economical basis; valuation of raw materials; food analysis, and disputed points in regard to adulteration, labeling, and the enforcement of pure food laws; bacteriological and enzymatic examinations, including fermentation tests, pure yeast cultures, beverages of all kinds; development of chemical inventions and industrial processes; examinations and advice on special machinery.

Inquiries of a minor character will be answered on this page, while major matters involving personal investigations, analyses, etc., will, if desired, be treated confidentially through the mails. All questions, materials for analysis, or letters leading to the opening of negotiations for special work will receive prompt attention if addressed to

CHARLES B. DAVIS,
Care of "The Chemical Engineer," 118 East 28th Street,
New York City.

S. C. D.—Under separate cover I am forwarding you the complete details for your plant apparatus. For the heating kettle I have made provision for copper coils, since you desire to obtain quick changes of temperature.

The number of linear feet quoted will be found ample to temper the size charge you are going to treat.

As soon as I complete the working formula covering the process, I will make you a personal visit. In the meantime you will proceed with the plant erection.

L. S.—The samples of intermediates for the production of your Azo Dyes have arrived, and I shall proceed at once to test their purity and forward the results of my analysis at the earliest opportunity.

A. A. F.—The "Liquid Fire" used in the present war is a mixture of equal proportions of coal tar benzol and crude oil, contained in a tank under a pressure of 300 pounds per square inch of nitrogen gas. Nitrogen gas is used because it is inert to the oils.

W. A. S.—The price of aluminum as approved by the War Industries Board, is 32 cents a pound. This price is for lots of fifty tons and over, in the form of ingots, and of 98 to 99% grade.

W. B. P.—Salad oils of the type you mention in your letter are composed chiefly of a mixture of olive and cottonseed oils, or entirely of this latter ingredient. Send four ounce samples for the analysis, and I will forward results and opinion as to purity in a week or ten days.

K. T.—Yes, it is possible to produce pure BaO^2 by reducing the pure carbonate to ozid at red heat, and then reheating in an atmosphere of air, or better, pure oxygen.

A careful regulation of temperatures is absolutely essential.

J. W. K.—In accordance with your request, I have purchased in open market a sample of the skin salve mentioned, and on chemical analysis it shows the following composition:

Calomel	1.60%
Petroleum jelly	85.00
Mercuric Oxid	7.60
Water	5.80
	100.00

The mercuric oxid ingredient is poisonous to the skin, and I strongly condemn it for use as a salve.

E. T. D.—Your auto oil contains too much carbon and will foul your engine. The "flash point" and viscosity are also too high for proper combustion. You had better send me a few samples so that I may be in a position to advise you as to which to purchase in the future.

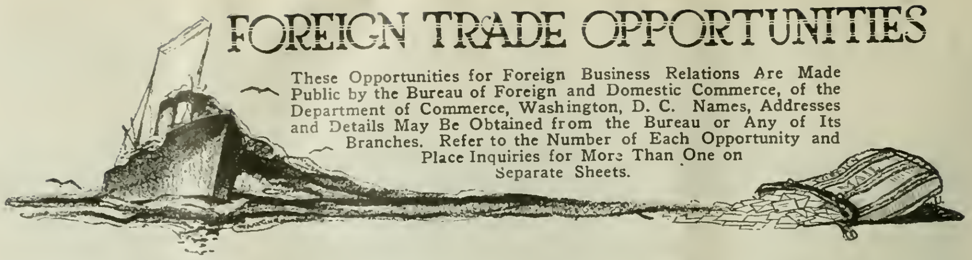
W. A. S.—Your request for the analysis of Pinus Palustris is given in full below:

Cellulose	58.48
Volatile Oil	1.30
Methyl Pentosan	3.60
Pentosan	7.46
Methoxy Groups	5.05
Soluble in 1% NaOH	22.36
" " Ether	6.32
" " Hot Water	7.15
" " Cold Water	6.20
Ash	0.37
Acetic Acid by Hydrolysis with 2.5% H_2SO_4	0.76

I have forwarded you the plans for the machinery, etc., under separate cover.

Charles B. Davis.

Those whose inquiries to this department have not as yet received attention must bear in mind that unless replies by mail are specifically requested, communications can only be considered in the order of their receipt.—Editor.



FOREIGN TRADE OPPORTUNITIES

These Opportunities for Foreign Business Relations Are Made Public by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce, Washington, D. C. Names, Addresses and Details May Be Obtained from the Bureau or Any of Its Branches. Refer to the Number of Each Opportunity and Place Inquiries for More Than One on Separate Sheets.

Chemical Products.

26761.—An agency is desired by a man in Italy for the sale of machinery, chemical products, hardware, saws, etc. Correspondence may be in English.

Soaps and Perfumes.

26703.—An agency is desired by a firm in Ireland for the sale of toilet soaps and perfumery of all kinds. Quotations should be made f. o. b. Atlantic port. Goods should be packed in strong cases. Reference.

Chemical and Pharmateutical Products.

26683.—An agency is desired by a man in Italy for the sale of chemical, pharmaceutical and industrial products. Correspondence may be in English. References.

Tanning Extracts and Chemicals.

26684—A company in Switzerland wishes to purchase tanning extracts and chemicals used for tanning, fish oil, paraffin, alum, stearin, etc. Quotations should be made f. o. b. New York. Payment will be made by cash against documents. Correspondence may be in English. References.

Cement, Paints and Soap.

26642.—A company in Jamaica desires to buy and secure an agency for the sale of large quantities of hand forks, hoes, horseshoe nails, wire nails, tin, machetes, lumber, cement, paints, laundry soap, and bar iron. Correspondence may be in English.

Chemical Products and Oils.

26697.—A firm in Argentina desires to represent American manufacturers and exporters of canned goods cottenseed oil, lubricating oils, drugs, chemical products, sugar, canvas, jute bagging, string, rope, firearms, staves, boots and shoes, hardware, electrical supplies, and other goods. Correspondence should be in Spanish or Italian. References.

Greases, Oils and Kerosene.

26638.—An agency is desired by a man in France for sale of automobiles, motor trucks, motorcycles and accessories, industrial engines, agricultural machines and implements, machine tools, sewing machines, typewriters, hardware, industrial supplies, greases and oils, and kerosene. Payment will be made on delivery. Correspondence should be in French. References.

Chemical Products.

26754.—An agency is desired by a man in Italy for the sale of machinery and chemical products. Correspondence may be in English. References.

Anilines.

26755.—A company in Brazil wishes to secure exclusive agencies for the sale of tissues of all kinds, anilines, and preserved foodstuffs. Sample must be submitted in order to properly bring the goods to the attention of Brazilian firms.

Oils.

26691.—A man in Canada desires to purchase and secure an agency for the sale of cylinder and automobile oils of the best grade. Quotations may be made f. o. b. Boston. Correspondence may be in English Reference.

Chemicals and Carbon Black.

26702.—A firm in Switzerland is in the market for carbon black for printers, and chemicals for medicine and technical purposes, in large quantities. Payment will be made by cash against documents. Correspondence may be in English. Reference.

Papers and Parchment.

26632.—A man in Switzerland desires to purchase or secure an agency for the sale of colored silk paper, parchment, and all kinds of paper. Samples of the kind of papers desired may be examined at the Bureau or its district offices. (Refer to file No. 98355.) Correspondence may be in English. Reference.

Textiles, Paints, Chemicals, Etc.

26606.—A firm in Colombia desires to represent on a commission basis American manufacturers and exporters of woolen, cotton, and silk cloth; office supplies; painters' brushes, paints, varnishes, etc., in paste or powdered; chemicals and drugs; glassware, chinaware, stoneware, etc.; articles of plated silver, silver, and sterling silver; toys; canned goods, such as meats, fish, vegetables, fruits, etc.; clothing for children; articles for the manufacture of imitation jewels; hardware; gutter tiles; carpets and rugs; automobiles and accessories; knives, forks, and spoons; paper of all kinds; underwear; hats; ribbons; artificial flowers; window glass; and articles of aluminum ware. Reference.

DISTILLATES

News Notes of Chemical and Allied Industries

To Rebuild Sulphite Mill.

Preparations are being made to rebuild the sulphite mill at the plant of the International Paper Co., Watertown, N. Y., which was recently destroyed by fire with an estimated loss of $100,000.

Arthur Howe With Duriron Co.

The Duriron Castings Co. has secured the services of Arthur Howe, whose work in connection with the manufacture of acids and explosives is well known, in the capacity of consultant.

Chemists' Club's New Officers.

Officers elected for the coming year at the recent annual meeting of the Chemists' Club, New York City, are as follows: President, Ellwood Hendrick; Vice-President, Dr. Chas. H. Herty; non-resident Vice-President, Chas. L. Parsons; Secretary, John R. MacPherson Klotz; Treasurer, Henry M. Toch.

Dr. Homberger to Instruct at Louisville.

Dr. A. W. Homberger, head of the chemistry department of Wesleyan University, has resigned to take up his duties next fall as Dean of the chemistry department at the University of Louisville, Ky.

Atwater in Governmental Work.

Active duties as consulting engineer in connection with the Government nitrate plant of the Ordnance Department, U. S. A., are now taking the attention of C. G. Atwater, manager of the Agricultural Department of the Barrett Co., New York.

Industrial Filtration Papers.

The H. Reeve Angel Company have just launched the expansion of their filter papers department for manufacturing requirements. The Angel company have long been specialists in filtering materials, and the chemical engineer can consult them on his requirements with full confidence.

New Color and Chemical Plant.

Metro Color and Chemical Works has been incorporated with a capital of $75,000, to operate plant for the manufacture of chemicals and dyestuffs at Brooklyn, N. Y. The incorporators are A. Petersen, M. Goldhammer and R. Jensen, Brooklyn.

To Manufacture Chemicals.

With a capital of $500,000 the Brown Chemical Co. has been incorporated at Maplewood, N. J., to manufacture chemicals and allied specialties, by Oscar G. Brown, F. M. Brown, Maplewood, and Arthur C. Hamilton, West Orange, N. J.

McKerrow Vice-President of New Concern.

H. Gardner McKerrow, of E. F. Drew & Co., Inc., New York, to whose energy was chiefly due the uniting of the American dye industry, has been chosen vice-president of the recently incorporated Knickerbocker Dyestuff Co., New York.

Smith Returns to Permutit Co.

Albert Tate Smith, recently manager of the R. U. V. Co., manufacturers of ultra violet ray apparatus, has resigned to return to the Permutit Co., with which he was formerly associated, to act as assistant manager of sales.

Knickerbocker Dyestuff Co.

Capitalized at $10,000, the Knickerbocker Dyestuff Co. has been incorporated under the laws of New York to engage in the manufacture of dyestuffs, etc. The incorporators are M. Mackenzie, A. H. Gleason and J. J. Hayden, New York City. This company has already placed upon the market a new chrome brown described on another page of this issue. E. F. Drew & Co., Inc., are the agents.

Chemical Machinery and Equipment.

H. E. Jacoby has devoted a number of years to chemical machinery and equipment problems, and has developed a contact with various sources of supplies which enables him to get at equipment quickly. His experiences along these lines should be of value to departments contemplating expansion.

American Business—Attention!

The First of Every Month

will be observed as

Thrift Stamp Day
In The U. S. A.

The first Thrift Stamp Day went over big! It proved a tremendous boost for Uncle Sam's Thrift Stamps and War Savings Stamps campaign and for American business in general. As a result of the great success of the first Thrift Stamp Day, it has been decided to make the First Day of every month Thrift Stamp Day in the U. S. A.!

This means that every branch of American business has the unusual opportunity to make the first of every month a **red letter business day** throughout the Nation, and a **Victory day for the U. S. Government** by disposing of hundreds of thousands of dollars' worth of Thrift Stamps and War Savings Stamps!

So get busy at once in preparation for these red letter business days these monthly Thrift Stamp Days! Manufacturers, jobbers, wholesalers, retailers, get together and plan for special Thrift Stamp Day sales, unusual values in every line of merchandise and commodity. It's up to you to help the Government and help yourselves at the same time.

Profit by your experiences of the first Thrift Stamp Day to make the succeeding Thrift Stamp Days still more of a success! Redouble the results! If any of you should still be unfamiliar with the working plan for Thrift Stamp Day, write for this plan **today without fail.** Address W. Ward Smith, National War Savings Committee, 51 Chambers St., New York City.

FEBRUARY-MARCH, 1917 AUGUST, 1917

Address Editor, 118 E. 28th Street, New York City

Our New Factory for the Manufacture of Pure Fused Silica, known as

SiDiO

has just been opened in New York City. A part of the output has already been assigned to the Government, but production is on such a scale as will enable us to meet your needs promptly.

SIDIO Ware is coming into wide use, both because of its low cost compared to platinum and other wares which it replaces, and also because of its technical superiority.

SIDIO withstands rapid temperature changes, it may be exposed to a continuous temperature of 1200° C. SIDIO has a coefficient of expansion one-seventeenth that of glass or platinum.

SIDIO is especially adapted for Combustion and Pyrometer Tubes, Sulphuric and Nitric Acid Condensing and Cooling Apparatus, high temperature gas analyses.

Chemical wares for the Laboratory made of pure fused silica, known as SIDIO, will give you added efficiency because of its low cost and technical superiority.

Get in touch with us at once so that you may benefit by the use of SIDIO Ware in your laboratory.

THE SIDIO COMPANY OF AMERICA, Inc.

37-39 MURRAY STREET, NEW YORK CITY

Cornered!

WE have no corner on Chemical Stoneware quality, yet we have it cornered—backed into a tight place where it can't get away from us—at bay.

In other words, we have put the kibosh on mere cost. The price you pay for General Ceramics ware is fair price, based on the very best Chemical Stoneware that anyone in all the world has ever been able to make.

That's what you get when you order G. C. Ware. You also get prompt action, and in case your order is large, you are enabled to draw upon the enormous facilities of our big plant.

General Ceramics Company

50 Church St., New York City

Western Sales Office: 112 W. Adams St., Chicago

See our exhibit at the Fourth National Exposition of Chemical Industries, Grand Central Palace, week of September 23rd.

Bring Us Your Dyestuff Problems

The application of dyestuffs to textiles is as important as their production. The technique of this branch of the color industry has for years commanded the best talent among those dyestuff distributors who have catered to the highest class of trade.

An intimate knowledge of the possibilities of every dyestuff is often necessary to meet the particular requirements of the consumer. Dyeing is a chemical, not a mechanical, process, and the variation of local conditions, due to differences in quality of water, steam and chemicals, makes the dyehouse problem an individual one.

Such problems are welcomed by the technical department of this company, which is manned by chemists who have been picked because of their knowledge, practical experience and demonstrated ability. We have long maintained well-equipped laboratories at our different offices for this purpose, and invite inquiries and extend, without any obligation on the part of our customers, our services to all who stand in need of them.

Checkmate!

Word has come from the western front that the Allies have discovered a new gas which neutralizes the effects of poisonous vapors employed by the Germans. According to the report, a barrage of shells filled with the new gas laid down in the sector flooded with the poison gas immediately purifies the atmosphere and renders the German clouds harmless.

This report has not been confirmed and does not state whether the new gas is effective against one, or two, or all of the fourteen-odd varieties of gases known to have been employed by the Hun in his efforts to make the world unsafe for democracy. Nor is it likely, in case it is true, that we shall hear much more about it, at least for some time to come, for it is necessarily the policy of the Government to exercise the most rigid form of censorship with respect to matters of this sort.

But assuming the truth of the report, then it becomes at once apparent that the effect upon the campaign in the western theatre of war will be most far-reaching. The Allies have long been retaliating in kind upon the Germans for their gas attacks, but consider the advantages of an army which is not only able to do this, but to render the enemy attacks fruitless!

Speaking of gas warfare, a member of the British mission to this country last winter declared that the chemists of both sides were working continuously to devise a colorless, odorless, and at the same time deadly gas. He stated that the side which first succeeded in doing this would almost certainly win the war. He also averred that the side which first compelled the other to adopt oxygen respirators as a defensive measure against gas attacks would practically drive their opponents out of the trenches.

Chlorine was the first gas used by the Germans, and within three days after the word had reached London, more than a million masks, made by the women of England, were on their way to the Allies' trenches. Other and still more deadly or irritating gases followed, and each time the Allies were able to develop suitable masks. Even the mustard gas, which caused men to vomit inside their helmets and rendered those affected virtually helpless before the Germans' subsequent charges, was at length overcome. When the enemy forsook the gas cloud for the gas-filled shell, the Allies again countered by adopting similar methods and issuing new orders about the wearing of masks continually while within certain zones. And so, at every stage of the struggle, the laboratories of both sides have been of vital importance and the chemists of the Allies have checkmated their opponents.

Defensive measures have kept pace with the offensive to such an extent that of late the best the Germans could hope for was to cause the Allies the inconvenience of wearing their masks while an attack was on—a situation which they were themselves in—or possibly to take the Allies unawares. If the present report is true, it would appear that their chemists now have by far the better of the battle of wits. The crowning achievement will come when someone of us devises a gas "invisible, odorless, and heavy enough to settle in the German trenches." It would save thousands of lives on both sides by ending the war almost immediately.

Government Mobilization of Technical Men

It is extremely gratifying to note that within the past month, two fresh evidences of an increased tendency on the part of the Government to watch over and supervise our chemical industries are reported. These evidences take the form of official announcements to the effect that the organization of the eagerly awaited "Chemical Warfare Service" has been completed, and that the War Industries Board has created two new divisions, to be known respectively as the "Chemicals Division," and the "Explosive Division."

The former organization will devote itself particularly to the control and development of all phases of gas warfare, and will be under the command of Maj. Gen. William L. Sibert. The two new divisions created by the War Industries Board will have under their official wings the production of the necessities indicated by their titles. Charles H. MacDowell, who was formerly chief of the "Chemical Section" of the Board, will be Director of the newly organized Chemicals Division, while M. F. Chase has been named to act as Director of the Explosives Division.

Newly drafted chemists will henceforth be immediately assigned to the Chemical Warfare Service, while all chemists now in the army will be removed from their units and placed under its authority. Some further idea of the scope of the new body can be gained by a perusal of Secretary Baker's announcement:

Heretofore chemical warfare has been carried on by divisions in the Medical Department, the Ordnance Department, and the Bureau of Mines. All officers and men who have been connected with offensive or defensive gas warfare here will be responsible to the Chemical Warfare Service. The field training section at present is under the Corps of Engineers.

Defensive warfare has been under the control of the Medical Department. This work has consisted of the designing and manufacture of masks both for men and animals and the procurement of appliances for clearing trenches and dugouts of gas.

Offensive gas warfare consists principally of manufacturing gases and filling gas shells. The work has been under the direction of the Ordance Department.

The new department will take over the work of chemical research for new gases and protection against known gases which has been carried on by the Bureau of Mines. All testing and experiment stations will be under the direction of the Chemical Warfare Service.

The responsibility of providing chemists for all branches of the Government and assisting in the procurement of chemists for industries essential to the success of the war and Government has been intrusted to the Chemical Warfare Service.

Authority to assign enlisted or commissioned chemists to establishments manufacturing for the Government has been granted to the new section.

The Chemicals Division will be subdivided into sections to handle the various commodities with which it is concerned, the chiefs of which will be as follows:

Acids and Chemicals—Albert R. Brucker, Russell S. Hubbard, and A. E. Wells.

Artificial and Vegetable Dyes—Dr. J. F. Schoellkopf, Jr.

Alkali and Chlorine—H. G. Carrell.

Asbestos, Chemical Glass, and Stoneware—Robert M. Torrence.

Coal Tar Products, (benzol, toluol, etc., including commandeering and allocation of toluol)—J. M. Morehead, Ira C. Darling, associate.

Rare Gases, Nitrogen and Oxygen—Chief not named.

Creosote—Ira C. Darling.

Electrodes and Abrasives—Henry C. Dubois.

Ethyl Alcohol, (molasses and grain)—William G. Woolfolk.

Ferro-alloys, (chrome, manganese, and tungsten ores)—Hugh W. Sanford, C. D. Tripp, J. H. McKenzie.

Fine Chemicals—A. G. Rosengarten.

Nitrates—Charles H. MacDowell, J. A. Bocker.

Paint and Pigment—Russell S. Hubbard.

Platinum—C. H. Conner, R. H. Carleton, G. I. DeNike.

Refractories—Charles Catlett.

Sulphur and Pyrites—William G. Woolfolk, A. E. Wells.

Tanning Material, (including inedible oils, fats, and waxes)—E. J. Haley, E. A. Prosser, Frank Whitney, Harold G. Wood.

Technical and Consulting—Dr. E. R. Weidlein, Dr. Herbert E. Moody, Dr. Thomas P. McCutcheon.

Wood Chemicals—C. H. Conner, A. H. Smith, R. D. Walker, Frank Whitney.

Statistics, Chemical (joint office)—Captain Willis B. Rice, army; Lieutenant M. R. Gordon, army; Assistant Paymaster Raymond P. Dunning, navy; Arthur Minnick, Chemicals Division.

A representative of the army, the navy, the Marine Corps, and other departments had been assigned to each section, and, with the Commodity Chief constitute the sections' membership.

In the Explosive Division, Mr. Chase co-ordinates with representatives of the army, the navy, and other departments concerned, and consults with the various section chiefs of the Chemicals Division.

The Chemical Exposition—An Institution

No longer is it necessary to explain why chemical expositions are beneficial, not alone to technical men and all others immediately concerned, but to the country at large. No longer is it necessary to paw the air for adjectives calculated to inspire the vacillating ones to "make up their minds to attend (or exhibit) and hang the expense!"

"Ballyhoo" methods were all very well in their place, which was the old-fashioned county fair where the guileless but extremely cautious rustic required considerable wheedling before he would consent to step up and point out just which shell the little green pea *wasn't* under, or, perhaps, part with a dime in order to feast his eyes upon the tattooed man, bearded lady, living skeleton, et al.

Were P. T. Barnum alive today he would discover that his public no longer delighted in being "fooled." A change has taken place, due in large measure to the sobering effect of a world-wide and bloody struggle for freedom from oppression, which would doubtless cause the great showman to blink his eyes. And for this reason educational events of the character of the National Exposition of Chemical Industries, the fourth of which is rapidly approaching, have now become as much of an institution with us as our elections, taxes or daily papers.

This year will see but two classes of the chemical fraternity contemplating the forthcoming event at the Grand Central Palace, New York City—those who are going, and those who are prevented from going by Government work. And among the potential exhibitors will be those who have booths and those who failed to make application in time. There is no indecision to overcome, we take it; there are no heathen to convert, and hence any eloquence which might otherwise have been employed for this purpose will be saved for the advent of the Fourth Liberty Loan.

The permanent slogan adopted by the managers: "Expositions are the timekeepers of progress," has taken on an added significance for us since it was first uttered by President McKinley. And the progress of our chemical industries during the past year, when graphically demonstrated in its entirety next September, will, we venture, be something to startle even those who have been in close touch with one or more phases of it.

The motion picture and conference hall will be located at the extreme rear of the third floor. Close to the entrance, as was the case last year, The Chemical Engineer will have a reception booth at which we hope to welcome many of our friends who seized the opportunity to pay their respects in person at the exposition of 1917. All visitors to the show are cordially invited to make this booth their headquarters and are hereby assured of a hearty welcome, together with whatever services or information it may be within our power to furnish.

The program of motion pictures to be presented is expected to furnish several surprises, although it is not yet in final shape for a detailed announcement. However, it is rumored that one or two of the largest exhibitors are laying plans for several unusual "stunts" in the shape of films especially prepared for first run at the exposition. These are said to be quite out of the ordinary. Specific subjects to be dealt with in the general motion picture program, the titles of which are to be announced later, will be Potash, General Chemical Engineering, Acids, including nitric and sulphuric; the Ceramic industries, and possibly the Metal industries. Special groups of films will also be shown, taking up in detail such subjects as recent progress in the development and application of our water-power, carelessness in the industries, with its attendant destruction of life, wealth and resources; recent progress in the oil industries, etc.

Altogether, the forthcoming Chemical Exposition bids fair to become a worthy offspring of its forbears of preceding years, and to offer a true index of the steady march of progress.

"Too Many Cooks . . . ?"

Do they? Some years ago the late John Jacob Astor advanced the opinion that should any technical achievement within the limits of physical or chemical laws, as we understand the terms, suddenly become of supreme importance to the welfare of the human race, a sufficiently large number of our scientists had only to devote their united abilities to it, and its accomplishment was assured.

The propounder of the above evidently took little stock in the saying that "too many cooks spoil the broth." He believed the reverse to be true, and was at some pains to point out the vast number of inventions which had germinated and languished for years in the brains of individuals, and which had refused to sprout further until some accident or sudden need turned the attention of many to the problem.

The present war has seen this principle beautifully illustrated again and again, and after the white flag has been hung out at one of the windows in a certain Palace in the Wilhelmstrasse, it is to be hoped that its role in speeding up the progress of the world will be even more fully understood. A contemplation of history repeals how surprisingly few of the truly epochal scientific achievements—by which is *not* meant "discoveries"—are the products of any one mind. Also, it appears to be true that the length of time consumed in working out such achievements varies, as a rule, inversely with the number of minds at work upon them.

Another example has just been added to the list. In these days, when one accomplishment follows upon the heels of another so rapidly as to almost bewilder the student of affairs, it will attract little or no attention. And indeed, it is not in itself a marvel at all; it serves rather to illustrate the rapidity with which a battery of trained minds, not one of which is necessarily a genius, as opposed to the old-fashioned "inventor," can develop new combinations of the elements to fill suddenly created wants. Not so many months ago the problem just solved by co-operative effort did not exist, and even the possibility that it might exist had never occurred save, likely, as mere idle speculation on the part of a very few.

Announcement has been made that the concrete ships being constructed by the Emergency Fleet Corporation will now come more directly into competition with steel ships as the result of the evolution of a novel protective coating, according to R. J. Wig, chief engineer of the Concrete Ship Division of the corporation. The nature of the new coating must, of course, be kept secret, but its evolution has resulted from the combined efforts of the engineers who are devoting their entire time and energies to perfecting this type of vessel.

In a statement regarding the new discovery, Mr. Wig said recently: "From our comprehensive tests of concrete structures at seawater we are assured that concrete ships will last a minimum of several years without any protection whatever. By the application of protective coatings, which are well known to us, we are certain of an extended life of several years additional, and with the further development of protective means upon which we are now working, I believe the concrete ship can be made as permanent as steel, if not more so."

Mr. Wig's earnest desire to quash immediately a false rumor now current regarding the life of concrete ships, will be shared by all who are alive to the harm which inevitably follows any addition to the already overwhelming maze of contradictions and inaccuracies which breed distruct in the abilities of those who direct our war industries. He states that: "At a meeting of the American Concrete Institute, held recently at Atlantic City, I was unfortunately misquoted as saying that the concrete ship would last only one year. Of course, this is not so nor did I say it, and I am anxious to have this erroneous statement corrected as soon as possible, because it puts the concrete ship in an utterly false position.

"The many able engineers who are now devoting their time to the study of concrete in our own organization are becoming more and more enthusiastic over the future of concrete ships. Improvements are constantly being made which make concrete more suitable for shipbuilding.

"Few people realize that the concrete ship is actually 20 per cent. lighter than the wood ship, if built of a new concrete mixture developed by the Emergency Fleet Corporation. The aggregate from which this new concrete is made is so light that it floats on water, and yet it makes a kind of concrete possessing twice the strength of that used in ordinary building construction. With this development, the concrete ship will come into more direct competition with the steel ship.

There are many problems yet to be solved in the building of concrete ships, and while this new industry sprung into life as an emergency war measure, its future is becoming more and more established as a permanent institution."

And to this, without question, will be added many others born of stern necessity and the focussing of many minds upon a given problem. The lesson is plain, and may profitably be applied here after the present stimulus is a thing of the past. How much longer might the need referred to have gone unfilled with only one or two men working—and independently of each other, at that—to devise a solution? Germany early learned the virtues of the plan and we marvelled at her results. Persistently applied among us, and aided by proverbial Yankee ingenuity, the possibilities of the future are scarcely to be measured by terms that we could have understood a short decade ago.

The Use of Gas

For Laboratories, Isolated Factories, Homes and Stores. Its Advantages in Heating, Cooking and Lighting.

By William A. Charters.

There is nothing that excels gas for use in the laboratories of factories for operating Bunsen burners, sterilizers, warming closets, auto claves, blast furnaces, forges, incubators, heating and lighting.

Concerns having laboratories or factories and people living out of reach of the public service gas mains and who, therefore, consider gas as altogether beyond their reach and something that they could only wish for yet never obtain, will be interested in the Equalizing gas machine manufactured by the Tirrill Gas Machine Lighting Co., 103 Park avenue, New York City.

For over fifty years this company has been manufacturing their gas machines, burners and appliances for some of the best known and critical concerns in the country, such as the U. S. Dept. of Agriculture, Bureau of Soils, Dept. of Chemistry, West Point, N. Y.; Agricultural Experiment Station, Mayagnez, Porto Rico; Dr. W. S. Wiley, Analytical and Consulting Engineer; A. H. Smith, president N. Y. C. & H. R. R.; Du Pont Powder Co., Atlas Powder Co., Government Base Hospital, U. S. Navy Yards; Procter & Gamble Mfg. Co.;

(*Concluded on page 306.*)

WATERPROOFING TEXTILES FOR MILITARY USE

By HERBERT P. PEARSON and FRED. SUNDERMANN, JR.[*]

Misconception regarding the term waterproofing and the waterproofing industry is responsible for two unfortunate facts. The United States soldier is clothed in materials which absorb water nearly as easily as the paper you blot your signature with and the Textile Industry in general is ignoring the resistance to such absorption as an important factor in the Conservation of Wool.

The reason for this condition of affairs is that the minds of nearly all army officials and of some textile experts are clouded with the idea that to make a fabric water-resistant is to waterproof it and that to waterproof it, is to close up its pores and change its appearance and other properties.

They are right about the effects of waterproofing because, as the dictionary tells us, a waterproofed fabric is one that is impervious to water, and you can't make a textile fabric impervious without closing up the *holes* that are in it,—that is to say, the spaces between the fibres.

Even the company we have the honor to represent has not as yet succeeded in making a hole impervious to water!

Where the responsible parties go wrong—and it sometimes takes thirty minutes personal lecturing to make them see that they *may* be wrong—is in assuming that a fabric cannot be benefited in the direction of waterproofing without being waterproofed.

We propose to demonstrate how without change of appearance or filling up of pores, the woolen fabrics used in army uniforms and overcoats are being successfully processed to make them much less absorbent, much quicker to dry when wetted, and possess much better wearing quality, by the simple means of treating the fabric in order to lower the surface tension of the fibres as compared with that of water.

To these processes we are attaching the name "water-resisting" and to the fabrics processed the term "water-resistant" to distinguish them from waterproofing processes and impervious fabrics.

Right here it would be well to state that many wearers of raincoats made of fabrics, the pores of which are not closed, are deceived by the terms "shower-proof" and "rain-proof" under which they are sold.

A shower is rain anyway, and rain is water, which, if pressed hard enough into the fabric by the weight of the rain drops accompanied by the driving of the wind, will go through any porous fabric if the pressure is great enough to overcome its surface tension, even though it be lowered by a water-resisting process.

Even a raincoat made of rubberized fabrics is apt to let water through under the higher pressures induced by extreme weather if the rubberizing does not completely close the pores, or if the seams are not heavily enough cemented.

A more general understanding is necessary, therefore, of this simple law:—

The degree of resistance of a fibre to water is determined by the greatness of the difference between the surface tensions of the fibre and that of water, and by the force with which the water is applied to the fabric, perfect imperviousness being produced only by entirely closing the spaces between the fibres.

What then, may be asked, is the good of a water-resisting process on a fabric if it is not impervious under all conditions?

Without altering the appearance or adaptability of most textile fabrics the fibres can be impregnated with substances which lower their surface tension to water so much that they are quite difficult to wet and when wet, dry out very quickly owing to the lack of thorough wetting through of the fibres under ordinary adverse weather conditions.

This resistance to wetting is not all the effect that can be produced by this means, for with a fabric of suitable character a considerable resistance to the *penetration* of water can be procured.

A textile fabric may be said to consist of a surface full of holes of greater or less size. If the fabric be treated with a water-resisting process and water applied, the surface of the water covering these holes acquires a convex form. This convexity is sufficient to enable the surface tension of the water to resist the inward pressure of the water against the fabric. If the pressure be increased sufficiently, the radius of curvature will become less than the radius of the holes; the water will go through, and it will keep on going through so long as the pressure is maintained.

It is needless, therefore, to point out that to resist the great pressure of a large drop and prevent its penetration, the fabric must have as few and as small holes or pores in it as possible, and the water-resisting treatment must be such as to secure the greatest difference between the surface tension of the water and that of the treated fibre.

Thus, if the fabric is of the right kind and the water-resistance effectual, a garment may be made of it which will keep out rain to a very considerable degree. If the water-resistant fabric is of open weave, the pressure of a rain drop will cause it to go right through, but the fabric itself will not become wet either immediately or readily. To wet the fabric the tiny pores of the fibres themselves have to be penetrated, and this requires greater force than the mere pressure of ordinary rain drops. Open-weave fabrics of this sort can be produced which can only be thoroughly wet by applying repeated blows to water laid on the surface of the fabric or by dabbing repeatedly with a wet object.

---

[*] Respectively General Manager and Works Manager, The Cravenette Co., New York City. Presented before a meeting of the New York Section, American Chemical Society.

We know from the experience of many not strictly comparative wearing tests that this resistance to wetting increases the life of the fabric considerably, and we are at present conducting a series of wearing tests to demonstrate this beyond doubt and to arrive with some degree of accuracy at the extent of the increased wearing quality.

We have a number of woolen suits, some untreated and others made water-resistant, undergoing a comparative test in ordinary wear and the Quartermaster's Office of the War Department has given instructions for a comparative test of wool uniforms and overcoats. This latter is to be done by clothing a platoon of men with water-resisting coats and uniforms and another with garments made of the same cloth untreated.

Apart from our experiences, the theory of the lengthened life of the treated fabric is that the wool fibre on becoming wet changes its curl and on drying again resumed to a great extent its former state. This causes a movement in the fabric and a loosening of the yarns, which tends to weaken their resistance to friction, for it is common knowledge that a tightly-twisted yarn wears better than one of looser character.

We have made numerous tests of the reduction in the absorption power of wool and cotton by exposing samples to a shower with a thirty foot drop, hanging to drain and observing the increased weight and then the rate of drying. The following figures give some of the results obtained on wool fabrics. The drying referred to consisted of hanging for one hour in a warm room:—

A heavy mackinaw cloth, untreated, under a very heavy test absorbed 141% of water against 25% when treated, and after drying contained 101% against 9% when treated.

A heavy army overcoating under a light test absorbed 38% of water against 15% treated, and after drying contained 12% against 3% treated.

A thick, grey all-wool flannel under a heavy test absorbed 140% against 60% treated, and after drying contained 104% against 32% treated.

We estimate from these observations that a soldier caught in a winter downpour of rain is soon carrying about with him in his overcoat no less than 7 pounds of water, whereas if the fabric is made water-resistant the most he is likely to carry is three pounds, and it is obvious that this saving of weight means a great deal when on the march.

The processes through which fabrics are put to make them water-resistant are not expensive. They add less than 1% to the cost of a garment and even if they only increase the life of the garment 10%, there is a very obvious saving in dollars and cents at the end of a period during which old garments have been exchanged for new.

The resistance to wetting of a solid substance depends on the extent of the difference between the surface tension of the substance and that of the wetting liquid. The greater the difference the greater the resistance. Consequently in making fibres resist wetting it is necessary to treat them with substances having as low a surface tension as possible.

The object of the water-resister, as distinguished from the water-proofer, is to impregnate the fabric and the fibre of the fabric with such a substance, taking care that the substance has as high a melting point as possible in order to avoid the shifting of the protecting body under the influence of the sun. It is also necessary, and quite an expert task, to eliminate from the fabric beforehand any substance which might mix with the water-resisting agent and thus raise its surface tension.

In conversation with a member of your society the point was brought out by him that if all the American army uniforms had been made water-resistant, many a case of pneumonia among the soldiers might have been avoided.

While this may be somewhat exaggerated, it is, nevertheless, certain that to make it much less easy for a uniform to get wet and much easier for it to dry when wet, is to contribute to the health and efficiency of the soldier.

We submit therefore that it is in the interest both of military economy and efficiency, and of the Conservation of Wool, for every yard of wool fabric made up into every kind of garment during the war, to be subjected to a thorough and expert water-resisting process, and we shall be grateful for any assistance which will enable us to secure action in this direction from the responsible authorities.

Finally we may say that our company is willing to cooperate with the Government in every possible way with this end in view.

Leases H_2SO_4 Plant.

W. Gordon McCabe, of Charleston, N. C., has leased the sulphuric acid plant of the Independence Chemical Co., of Charlotte, N. C.

Two More Government Nitrate Plants.

Contracts for the construction of two plants for the manufacture of nitrates from the air, to be located at Elizabethtown, Ohio, and Toledo, Ohio, respectively, have been awarded by the Nitrate Division, Bureau of Ordnance, U. S. War Dept., to the Air Nitrate Corp., Madison Ave., New York City. The cost of the two will run into several million of dollars.

THE RECOVERY OF POTASH

As a By-Product in the Manufacture of Portland Cement

By
JOHN J. PORTER *

Prior to the war over 1,000,000 tons per year of potash salts were used in this country. This is equivalent to approximately 300,000 tons of pure potash and represents a value of about $18,000,000. There is every prospect that this consumption will be largely increased when a full supply of potash is again available.

Over 90 per cent. of our normal consumption of potash is used as fertilizer. Potash is one of the three elements essential to plant growth. It is present in small quantities in all soils and we can get along for a while on these reserves. Since it is removed from the soils by crops, however, it must be replaced and in the long run must be added. There is no substitute for this purpose.

Potash is also used in the form of pure salts in various chemical industries. The quantity required is not very large but it is very necessary, as in many cases no substitute is admissible.

For many years the world's supply of potash has come from natural deposits located near Stassfurt, Germany. It occurs there in beds associated with rock salt and gypsum and can be mined very cheaply. The German potash industry is controlled by the Government and all producers are required to sell through a syndicate whose policy has been to stifle competition in other countries by temporarily cutting prices. This they have been able to do because of their world market and low cost of production.

Cement Industry as Source of Potash.

With the outbreak of war, the world's supply of potash was at once cut off and the operation of many industries badly dislocated. In spite of the spur of high prices, the output of potash in this country in 1916 was less than 5 per cent. of its normal consumption and the majority of present producers can only continue to operate so long as prices remain at or near their present levels. It is probable that the cement industry, certain brine lakes and alunite will remain as permanent producers but their output as at present developed is only a drop in the bucket. Extensive explorations have not succeeded in locating anything similar to the German deposits in this country. Small deposits have been found in Spain and Abyssinia but considering the situation broadly, there is absolutely no relief in sight from the German potash monopoly unless it be through the co-operation of the cement industry.

The cement industry is undoubtedly the chief potential American source of potash, especially when considered in connection with the use of feldspar and other high potash materials. Based on available information, I estimate that the mills of this country, as at present operated, are capable of producing commercially about 100,000 tons per year of potash or about 33 per cent. of our normal requirements. The possibilities through the use of high potash materials are much greater.

All cement materials contain some potash. As a rule the purer limestones contain very little, say from 0.1% to 0.3% and from there running up to 1% and over in the argillaceous limestones. Many clays and shales contain as high as 3% and 4% potash.

In the raw mix as fed to the kilns, the potash varies from about .30% to 1.30% in the various mills of the country. Probably the average for the whole country will not be far from .75%; a small percentage to be sure, but equivalent, nevertheless, to 4.5 lbs. of potash entering the kilns for every barrel of clinker made or to 220,000 tons per year.

The profitable recovery of this potash is not simply the problem of collection but rather the problem of obtaining it in a sufficiently concentrated form to be salable and at a sufficiently low cost to leave a profit under normal market conditions. The three factors to be considered in this connection are first, liberation; second, recombination, and third, collection.

The potash in the raw mix remains partly in the clinker and in part is volatilized or liberated in the kilns and passes out with the stack gases. The percentage of the total potash so liberated varies in different mills and under different conditions from 25% to 95%. The average under usual operating conditions is probably about 50%. Our liberation at Security was originally about 40% but by various changes, we have increased it up to a present average of over 60% and for several weekly periods have obtained as high as 70%.

Problem of Liberation.

We have still much to learn regarding liberation but there is evidence so far that it can be increased by high lime, hard burning and by the addition of chlorides or fluorides to the raw mix. The use of calcium fluoride or fluorspar has been patented by Messrs. Huber and Reath and is in use at the plant of the Riverside Portland Cement Co. At Security we have developed the use of common salt (sodium chloride) for this purpose and by its use have greatly increased our liberation. I understand that a Western mill which is getting in regular operation 95% liberation is using a raw mix

---

*First Vice-Pres. and General Manager, Security Cement and Lime Co. Paper presented at a meeting of the Portland Cement Association.

containing naturally about 5% salt. If this is true, their high liberation is readily explained.

When we undertook the collection of potash we expected that practically all of our potash would be in a water soluble form. This expectation was based on the results obtained at Riverside where the Cottrell dust collection system had for some time been in operation. Naturally we were much disappointed after starting up our plant to find that the material collected contained a considerable proportion of potash in a form which was not readily soluble in water. As under trade customs prevailing in the fertilizer industry, we could not secure payment for this portion of the potash, it made a big difference in our profits and the matter was, therefore, most thoroughly investigated. We found that the trouble was due to the recombination of a portion of the volatilized potash with the finely divided ash of the coal as this floated through the back part of the kiln. This ash takes up potash vapor until it reaches a certain degree of saturation and the amount of potash so recombined is, therefore, roughly proportional to the amount of coal ash present in the gases. The amount of potash recombined will be approximately 10% of the weight of the ash present, or for our conditions as to fuel consumption and quality of coal, will be from .8 to .9 lb. of potash per bbl. of clinker.

I should explain that at Riverside, oil is used as fuel so that, in spite of the work done there, the real nature of the problem and the difficulties introduced through the use of coal as fuel were not fully understood when the Security Company started in the potash business.

Solubility of Potash.

Further work on this problem developed the fact that this recombined potash was not insoluble in water but was only very slowly soluble. It will all go into solution on boiling for 10 hours or by heating with water under 100 lbs. pressure for one hour. It is also different from the potash as contained in the original mix by being readily soluble in very dilute acids. It is, therefore, entirely possible to leach all of the recombined potash from the material collected.

Many methods have been tried for the purpose of preventing the recombination of the potash in the back part of the kilns, and our chemists, Messrs. Haff and Cheesman, have applied for a patent covering the use of salt in that connection. We have found it possible to considerably lessen the amount of recombination, but so far we have not been able to entirely eliminate it.

Electrical Precipitation Effective.

At Security we have made use of the Cottrell electrical precipitation method for the collection of our potash. Personally, I believe that this method is the best system, but I would not claim that it is the only possible method of collection. I have no first hand knowledge of the various water spray methods which have been advocated but I should expect that there would be some difficulty in getting a high percentage of collection with this type of apparatus.

We have found the Cottrell system highly satisfactory from an operating standpoint. The cost of operation has been low and it has given practically no trouble. Originally we caught about 95% of the dust and about 80% of the potash going to the treaters. Since we have been adding salt, however, we have not done so well on collection. It has been found that the presence of chlorine in the gases causes a considerable decrease in the electrical efficiency of the treater, but, nevertheless, we have found it very profitable to continue the use of salt because the increase in liberation has much more than counterbalanced the decrease in collection efficiency.

I might as well admit frankly that we have suffered the usual penalty of pioneers and have not gotten the best type of treater from the standpoint of potash collection. At the time our plans were made all treaters had been designed from the standpoint of dust collection and the importance of obtaining the potash in a concentrated form has not been developed. The Western Precipitation Company, owners of the Cottrell patents, and ourselves are now engaged in developing, and, in fact, installing at Security a new type of treater adapted particularly to the collection of potash. This type of treater can be built almost entirely of concrete or brick at a considerable saving in cost. It will operate on the principle of having a film of water flowing over the precipitating surface so that the material will be recovered in form of solution and slurry. It has been found that in the presence of a water film the difficulty due to the presence of chlorine or chlorides in the gases is entirely overcome and a very high efficiency of collection can be obtained. The water will be circulated through the treater until it becomes saturated with potash salts and these will then be recovered by a process of evaporation and crystallization.

The gravest error in the construction of our treater, however, was to precipitate all the dust and potash together in one hopper. It would have been just as easy to have arranged the treater on the principle of the original late treaters at Riverside. The dust could have been precipitated selectively, recovering the coarse dust containing but little of the potash in the first chamber and a concentrated potash material in subsequent chambers. This procedure would make the sale of the potash material vastly easier.

The quality of the material collected is inversely as its quantity. There is practically a fixed amount of potash caught per day and this is diluted with whatever raw mix is blown over from the kilns. It is extremely desirable from a sales standpoint to collect a high potash material and therefore, to keep down the amount of dust blown over or else to precipitate out the coarse dust first as suggested above. At Security our dust loss averages about 4% and I should judge that for the average cement plant, it will run close to 5%. The percentage of potash in our material as col-

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS[*]

PART XV

Mercury Lamps for Use in Spectroscopy, Polarimetry, and Saccharimetry.

The use of the mercury lamp in spectroscopy, polarimetry and saccharimetry is advocated by *Lowry* (Trans. Faraday Soc., 1912, *7*, 267). In spectroscopy no great intensity of light is needed, the light emitted from a vacuum tube being quite sufficient for taking readings with a spectroscope or with an instrument such as the Pulfrich refractometer. A mercury light of sufficient intensity for this work, Lowry states, can be produced very conveniently from a hydrogen tube containing a globule of the metal; this hydrogen-mercury tube has the advantage that it lights more easily than a tube containing mercury only, while by warming the globule, the spectrum of the metal can be made as bright as may be wished.

The problem of providing a source of light for use in polarimetry, he considers, much more difficult, on account of the fact that the intensity of the light is reduced to a small fraction of its original magnitude by the action of the Nicol prisms. The polarizing Nicol begins by eliminating half the light, and if the half-shadow angle of the instrument is set to 5° there is a further reduction to $\sin 2\frac{1}{2}° \times \frac{1}{2} = 0.0218$ at the "extinction" position. The intense light of the modern mercury lamp renders it exceptionally suitable for use in polarimetry, and it is now beginning to be employed to a considerable extent also in technical saccharimetry.

The chief advantages of the mercury light may be summarized as follows:[1]

1. The green line is of exceptional purity; a rotatory power of 5,000° can be read as easily as one of 5°; on the other hand, when sodium is used, the two lines, D_1 and D_2 do not extinguish together except in the case of small rotations.

2. The line can easily be separated from the other constituents of the spectrum by means of a direct vision prism of low power; no extra cost is involved in fitting this to the eyepiece of the polarimeter, as even sodium light cannot be used for accurate work unless some such method is used to purify the crude flame-spectrum.

3. On account of the great intensity of the light the half-shadow angle of the polarimeter may be reduced to 2°, 1° or less; the instrument then becomes exceedingly sensitive. Alternatively, cloudy or colored sugar syrups may be read with a half-shadow angle of moderate size.

4. The light is absolutely steady and may be kept running without interruption for a week at a time; all risk of change of zero through changed illumination is thereby avoided.

5. Contamination of the atmosphere and dirtying of the instrument by sodium salts are avoided.

6. The readings are usually at least 18 per cent. greater for mercury green than for sodium yellow light.

The credit of introducing the use of the mercury lamp in polarimetry, according to Lowry, belongs to Disch[*] and to Schönrock,[†] who made use of the Arons lamp. In 1906 Lowry introduced this method of illumination in his own laboratory; since that date the sodium light has been abolished, except when dispersion values are required, or when some comparison has to be made with observations made by the older methods. He states that mercury lamp is also being used at South Kensington and at Cambridge, and, when its advantages have been generally realized, will certainly be adopted as the ordinary method of illumination.

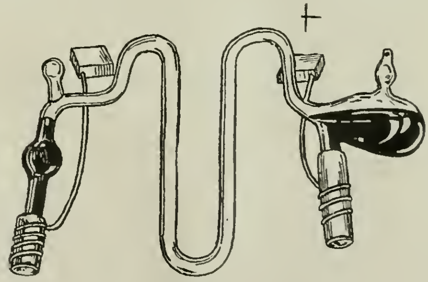

Fig. 1—The Bastian Glass Mercury Lamp.

Although no longer on the market, the Bastian glass mercury lamp (Fig. *1*) he regards the best for ordinary laboratory use. Its current consumption is small; no auxiliary resistances are required; the flex carrying the current to the lamp can be plugged into the ordinary lighting circuit without damaging the wires or blowing the fuses; and for work of high accuracy the light is found to be purer, and the continuous background to the spectrum far less intense, than in the case of the silica lamps of high power which have displaced it from commercial use. The lamp must be lighted, and is intended to burn with the zig-zag tube in a horizontal plane; but as soon as the tube is hot the lamp may be turned into a vertical plane and will burn in this position for some days without going out. It is then possible to focus one of the straight portions of the tube upon a vertical slit, thus producing an intense and uniform linear illumination.

Two forms of silica lamp have been designed for use with the polarimeter. The lamp shown in *Fig. 2* was designed in order to use the arc in the end-on position. In a lamp of this type the bulb on the right in the figure usually becomes covered with drops of condensed mercury; to avoid this a window of polished silica was mounted on a re-entrant tube in the center of the bulb where it is kept hot by the arc and remains clear and free from globules of mercury. The lamp takes a current of 3½ amperes and produces a very powerful light. It was found to be of very great service in taking polarimeter readings with the violet mercury line, when studying rotatory dispersion, the violet light being so intense that readings can be taken with a half-shadow angle of about 4° only.

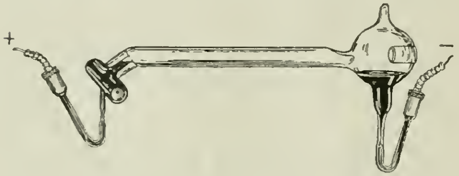

Fig. 2—Silica Lamp for Use in Polarimetry.

The chief disadvantage of the end-on lamp is that a slight displacement of the lamp may produce a marked alteration in the relative illuminations of different parts of the field of the polarimeter. The lamp must therefore be set very carefully if a constant zero-reading is to be maintained. This difficulty can be avoided by using a horizontal line of light to illuminate the polarimeter when the field is divided vertically, or a vertical line of light for a polarimeter in which the divisions are horizontal. Most of the commercial silica mercury lamps are arranged with a horizontal arc, and are therefore not suitable for use with aspectro-polarimeter in which the division of the field must be made horizontal. In order to overcome this difficulty the lamp shown in *Fig. 3* was devised. It is a modification of the commercial "Quartzlite" lamp and was constructed specially by the Brush Electrical Engineering Company for use in the vertical position. Two of the lamps used by Lowry for nearly a year and proved to be satisfactory in every respect. The line of light is very intense as the arc "pinches" into a narrow column (about ⅛-in. diameter) in the center of the tube. The only drawback to this concentration is the development of an appreciable quantity of continuous light, and a marked intensification of the weaker lines, demanding some additional care in the spectral purification of the yellow and violet lines.

Carbon Monoxide.

Berthelot and *Gaudechon* (Compt. rend., 1913, *157*, 129), have shown the aptitude of carbon monoxide to form additive products by its behavior towards certain gases under the influence of ultra violet light. In the presence of nitric oxide, a small proportion of the carbon monoxide is oxidized by the oxygen set free from the decomposition of the nitric oxide. With water the reaction is more complex, one part of the carbon monoxide combining directly with the water, yielding formic acid, while the rest combines with the hydrogen and oxygen, resulting from the dissociation of the water to give formaldehyde and carbon dioxide respectively. Of the halogens chlorine combines with carbon monoxide but bromine and iodine are without action. While combining with ammonia, chlorine is without action on hydrogen phosphide or arsenide, and does not react with hydrogen sulphide or free sulphur.

Decomposition of Carbon Dioxide.

The combination of carbon monoxide with oxygen in ultra violet light is found by *Herchefinkel* (Compt. rend., 1909, *149*, 395) to be reversible, considerable quantities of carbon monoxide being formed when dry carbon dioxide is exposed in quartz vessels, in the presence of mercury, to the action of the light. He confirms Cameron and Ramsay's observation that this decomposition is also effected radium emanation (J. Chem. Soc., Trans., 1908, *93*, 981).

Sulphur.

The manner in which the electrical conductivity of sulphur changes with the temperature varies according as the sulphur is crystalline or amorphous. The conductivity of crystalline sulphur increases with rise of temperature to a maximum at about 140-150°, and afterwards continues to fall until the boiling point is reached. With amorphous sulphur the conductivity falls as far as 140-150°, then increases up to 160-170°, after which temperature it falls continuously to the boiling point. With amorphous, but not with crystalline, sulphur the conductivity is increased by the action of light, this effect being caused more especially by rays of shorter wave-length than 280 $\mu\mu$. This phenomenon is conditioned by changes occurring in the sulphur, and by phenomena such as that of Hallwachs. (*Pigulewsky*, J. Russ. Phys. Chem. Soc., 1912, 44, Phys. Part, 102; J. Chem. Soc., 1912, Abs. 102, ii, 418.)

Colloidal Metals.

Commenting further on the formation of disperse systems by metals under the influence of ultra violet light and Rontgen rays, *Svedberg* (Zeitsch. Chem. Ind. Kolloide, 1910, 6, 129) states that the effect is greatly diminished if the active metals are superficially exodized. The quantity of the colloidal metal formed is proportional to the amount of radiation which falls on the surface of the metal. The mean size of the colloidal particles increases with increase in the time of exposure to the active rays; this is said to be due to an aggregation of the very small particles, which are formed primarily, under the influence of active radiation. The formation of the colloidal metal is unchanged when the metal is electrically charged. For a given metal the magnitude of the disintegrating effect is dependent on the nature of the dispersive medium in which the metal is immersed. It is much greater for ethyl alcohol than for ethyl ether. An exact comparison of the behavior of different media is, however, rendered difficult by the fact that these absorb the ultra violet rays to very different extents.

An examination of the dependence of the effect on the wave-length of the incident radiation indicates that colloidal formation is not produced to any sensible extent by rays of wave-lengths greater than about 405 to 410 $\mu\mu$. The phenomena are supposed to be due to the solvent action of the liquid on the metal, whereby small quantities of a chemical compound are found; under the influence of the ultra violet or Roentgen rays, this compound is decomposed, and the metal separated in the colloidal form. In support of this explanation, experiments are described which show that similar colloidal solutions are obtained when disks of the active metals are suspended immediately above the surface of the dispersive liquids and subjected to the action of the rays from a quartz mercury lamp. With lead and ethyl alcohol, the formation of a colloidal solution can be detected at the end of fifteen minutes. Svedberg supposes that the metal is acted on by the alcohol vapor and that the resulting compound dissolves in the liquid.

Action of Ultra Violet Light on Colloidal Gold.

Svedberg (Zeitsch. Chem. Ind. Kolloide, 1910, 6, 238) describes experiments which show that ultra violet rays have a considerable influence on the nature of the colloidal gold which is obtained by the action of reducing agents on solutions of gold salts. If a solution of chloroauric acid is made alkaline and reduced by means of hydrazine hydrochloride in the presence and absence of ultra violet rays, the colloidal gold which is obtained consists of very much smaller particles in the former case. The change in the character of the solution which is brought about by the ultra violet radiation disappears very slowly when the solution is kept in the dark before the reducing agent is added. Attention is called to the importance of these observations in connection with photo-chemistry.

Mercury.

The phosphorescence of mercury vapor has been observed by *Phillips* (Proc. Roy. Soc., 1913, A, 89, 39) by directing a beam of light λ = 2536 from water-cooled quartz mercury lamp on to an exhausted quartz tube, in which a stream of mercury vapor is produced by distilling mercury from one limb into the other. The mercury fluoresces at low pressures, and persists after the vapour has passed the exciting beam of light. The fluorescence of the vapours of iodine, anthracence, and retene was examined by the same method, but with negative results.

Glass.

Gortner (Amer. Chem. J., 1908, *39*, 157) exposed several specimens of glass from various sources to the direct action of the sun, and made following observations: Glass which is relatively rich in manganese (about 0.2 — 0.3%) becomes colored in less than a month, the degree of coloration being proportional to the manganese present. Most specimens of glass containing only a small proportion of manganese become colored in less than a year and the color becomes deeper if the time of exposure is increased. The production of this violet coloration is a proof of the presence of manganese, but some specimens of glass although containing this element, do not become colored. A violet background is more favorable to the action of ultra violet rays than any other color. White, yellow, red, and blue act alike, and seem to have no effect on the rate of coloration, while brown and black appear to have a retarding action.

Colors of Minerals.

A record of a large number of observations relating to the changes in color of various minerals and colored glasses on exposure to the action of radium rays and ultra violet light is given by *Doelter* (Monatsh., 1909, *30*, 179; J. Chem. Soc., 1909, Abs., *96*, ii, 363). It follows from the results obtained that, generally speaking, the coloring materials of minerals are not of an organic nature, the colors being due principally to the presence of oxides of iron, chromium and manganese. The change in color under the influence of radium rays is in many cases the outcome of a reducing action while the ultra violet rays have an oxidizing action; consequently ultra violet light and radium rays frequently induce opposite changes. The bearing of the results on the origin of the color of many minerals and precious stones is discussed.

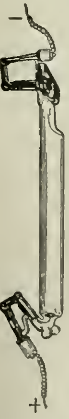

Fig. 3—Special Form of Lamp Designed for Use with Spectro-Polarimeter.

Fluorspars.

Experiments are described by *Meyer* (Ber. deut. physikal. Ges., 1908, *6*, 643; Physikal. Zeitsch., 1908, *9*, 810) the object of which was to determine the nature of the luminescence phenomena exhibited by certain blue fluorspars after exposure to light. During the decay of the thermo-luminescence, and for a considerable time after the disappearance of the visible effect, the emission of ultra violet photochemically active rays can be detected. The intensity of this radiation diminishes gradually, but in the case of fluorspar from Wolsendorf, in Bavaria, the ultra violet radiation could still be detected by the photographic action after the substance had been kept in the dark for one hundred and fifty days. If the fluorspars are heated at 230-260°, the luminescence properties are not developed by exposure to diffused daylight or to an arc lamp; on the other hand, they respond to the light from electric sparks or a mercury lamp even when heated to a bright red heat. The experiments also show that the intensity of the luminescent radiation increases with the length of the period of exposure to the primary radiation when this period is small. Above the certain limit the period of exposure has, however, no influence on the emitted radiation. There appears to be no connection between the effect examined by Meyer and the photo-electric activity.

Carbonyl Chloride.

Cohen and *Becker* (Ber., 1910, *43*, 130) find that when carbonyl chloride is passed through a quartz tube at the ordinary temperature, and at the same time submitted to the action of light from a mercury-quartz lamp, it is partly decomposed into carbon monoxide and chlorine. When 1 c. c. of carbonyl chloride is passed through the quartz tube (20 cm. long and 0.5 cm. in diameter) per minute, the amount of decomposition was 3.3-4%. The effect is chiefly due to the short ultra violet rays, since when tubes of Uviol glass were used, which are only transparent to waves of greater wave-length than 265 $\mu\mu$, the decomposition was only 0.46-0.5%. In ordinary glass tubes there was no decomposition. Coehn and Becker remark that in all the cases hitherto examined, namely, the photochemical equilibria of sulphur trioxide, hydrogen chloride, and carbonyl chloride, the actual equilibrium is affected only by ultra violet rays. Rays of greater wave-length simply act catalytically on the attainment equilibrium.

Iron Compounds.

The action of ultra violet light on ferric sulphate, nitrate and chloride is noted by *Ross* (J. Am. Chem. Soc., 1906, 790) who used an arc between aluminum electrodes as a source of ultra violet rays. The action of light on ferric salts is much increased by the presence of some organic compound as cane sugar which of itself will not reduce these salts but does so under the influence of light. Hence Ross employed a definite amount of sugar in the iron solutions which were exposed to light. The amount of ferric salt reduced is approximately proportional to the time of exposure. A 1/5 normal solution of ferric chloride containing 10 grams of sugar per 50 cc. of solution gave results as follows:

Time of exposure	$FeCl_2$ formed in cc. of 3 N/400 solution.
10 minutes	2.53
20 minutes	4.70
30 minutes	7.15

Varying the temperature of any ferric salt solution was found to have a slight effect on the rate of reduction.

Chloroplatinic Acid.

Boll (Compt. rend. 1913, *156*, 138; J. Chem. Soc., 1913, Abs., *104*, ii, 171) has studied the rate of hydrolysis of tetrachloroplatinic acid when submitted to rays of different energy. The light from a mercury-vapor lamp was dispersed by two quartz prisms, and certain of the resulting rays were used as a source of energy, the amount reaching the acid solution being controlled by a screen, consisting of a cell containing a dilute solution of caffeine, the concentration and thickness of the layer being varied.

Rotary Dispersive Power.

An account is given by *Lowry* (Proc. Roy. Soc., 1908, A, 81, 472; J. Chem. Soc., 1909, Abs., *96*, ii, 200) of improvements which have been made in the method of determining rotary dispersive power. As a result of these, the intense line spectra yielded by metallic arcs can be used for polarimetric measurements. For this purpose a parallel beam from the arc is thrown onto the slit of a constant deviation spectroscope. An achromatic lens, which is substituted for the observing tube, is used to throw a magnified image of the slit onto the polarizing prisms which give a triple field. By suitably adjusting the constant deviation prism, the whole field can be illuminated with monochromatic light of any desired wavelength. For observations with ultra violet light, an arc passed between a carbon and a magnetite electrode is used. A beam from this is thrown by a quartz condenser onto the field of the polarizing Foucault prisms, and by means of a quartz-calcite lens, substituted for the analyser-telescope a diminished image of the field is thrown on the slit of an ultra violet spectroscope. The spectrum is photographed, and the line, for which the intensity in the three parts of the field is the same, is identified on the negative.

Rotation of Plane of Polarization.

The magnetic rotation of the plane of polarization for ultra violet rays of different wave-lengths have been examined by *Sirks* (Physikal. Zeitsch., 1913, *14*, 336; J. Chem. Soc. 1913, Abs. *104*, ii, 458), who conducted experiments with oxygen, hydrogen, and carbon dioxide. In the case of oxygen, measurements of the rotation extend to $\lambda = 265.4$ of hydrogen to $\lambda = 237.8$, and of carbon dioxide to $\lambda = 248.2\ \mu\mu$. The rotation increases rapidly as the wave-length of the ultra violet light diminishes, and the values for the different gases appear to fit as satisfactorily with the data obtained by Siertsema for the rotation of rays in the visible spectrum. By combining the two series of results, and plotting the rotation (relative to the rotation for the yellow mercury line) as ordinate against wave-length as abscissa, it is shown that continuous curves are obtained in the case of each of the three gases. The curve for oxygen is much lower than the curves for the two other gases, and of these the hydrogen curve the higher. The observed magnetic rotation of ultra violet rays in hydrogen is shown to be at variance with the assumption that the action of the molecules on the ultra violet light can be referred to a single type of electron.

Change in Surface Tension.

A number of aqueous solutions of measured surface tension were subjected for either two or three minutes to the action of the light from a high-tension arc between aluminum electrodes by *Marenine* (J. Russ. Phys. Chem. Soc. 1913, 45, Phys. Part, 28-30; J. Chem. Soc. 1913, Abs. *104*, ii, 390), and their surface tensions then re-measured. Water and 3% magenta solution showed no change, 30% resorcinol solution showed a decrease of 9.6%, this being probably due to chemical changes; while 10% solutions of eosin, sodium sulphite and potassium permanganate, and also 1% methyl-violet and 20% potassium nitrate solution, showing increases in surface tension varying from 3.2 to 5.1%. Further measurements demonstrate that the increase in surface tension reaches a maximum approximately 1.5 minutes after the action of the light ceases. The surface tension subsequently falls continuously to the original value, which is sometimes attained only after thirty minutes. A quartz mercury lamp of great actinic power does not cause any such increase in the surface tension, and it seems likely that the phenomenon is due to an action of electrical character.

Ionisation.

In order to ascertain whether certain gases or vapours can be ionised at the ordinary temperature by ultra violet light of moderately long wave length, experiments have been made by *Hughes* (Proc. Camb. Phil. Soc., 1911, *16*, 376; J. Chem. Soc. 1912, Abs. 102, ii, 5) with carbon disulphide, carbon dioxide, stannic chloride, and zinc ethyl. In no case could ionisation be detected, although for the same amount of light energy, the leak from a zinc or carbon surface would have been about 106 times that of the smallest effect which was measurable with the arrangement of apparatus employed. Solid compounds of zinc and tin were found to be photo-electrically active.

Moreau (Compt. rend., 1902, *135*, 898) finds that conductivity of a flame containing salt at a constant temperature depends on the E. M. F., the distance between the electrodes, which consist of small, jat, platinum condensers plunged in the flame, and the concentration of the salt solution, the evaporation of which supplies the salt to the flame. The results show that there is no dissociation in the vapor of the salt before the introduction of the electrodes; the conductivity of the flame before the ionisation ocurring mainly at the negative electrode, and is thus analogous to the conductivity of gases in the neighborhood of a metal illuminated with ultra violet light.

Electrons.

Measurements have been made by *Hughes* (Phil. Trans., 1912, A., 212, 205; J. Chem. Soc., 1912, Abs., 102, ii, 883) of the maximum velocity with which photo-electrons are emitted from the surface of various metals subjected to the action of monochromatic ultra violet light. The surfaces were prepared by distillation of the metals in a liquid-air vacuum. The data obtained for calcium, magnesium, cadmium, zinc, lead, antimony, bismuth, and arsenic show that the energy of the fastest electrons is proportional to the frequency of the incident light.

In an investigation on the spectral extension of ultra violet vibrations and its relation to the different crystal systems, *Eisenmann* (Ber. Deut. physikal. Ges., 1912, *14*, 315; J. Chem. Soc., 1912, Abs., 102, ii, 506) has deduced expressions for the frequencies of vibration of the atom and electron, and these are applied in the calculation of the maximal energies for the atoms of different elements, assuming that the number of the neighboring atoms which exert an influence on the vibrations of a particular atom is dependent on the crystalline system to which the element in question belongs.

Photo-Electric Activity.

According to Hughes, dry zinc chloride shows no photo-electric activity, although photo-electric currents of considerable intensity are obtained with the moist substances. *Willows* (Phil. Mag., 1912 (iv), 24, 891; J. Chem. Soc., 1913; Abs., *104*, ii, 4), states that this observation is probably connected with the fact that the moist halogen salts of zinc emit large quantities of positive and negative ions when heated to 300°, whereas the dried salts are inactive. The halogen salts are evidently unstable, and ultra violet radiation in presence of moisture represents one of several agents, the action of which suffices to bring about decomposition.

The disintegrating effect which ultra violet light has been found to exert on gold leaf exposed to its action is shown by *Stark* (Physikal Zeitsch, 1908, 9, 894) to be in accordance with theoretical requirements. An experiment is described which appears to show that positively charged atoms are emitted in consequence of the absorption of ultra violet light.

Photo-Electric Effect of Various Compounds.

The emission of electrons by various solid compounds subjected to the action of ultra violet light has been investigated by *Hughes* (Phil. Mag., 1912 (vi), 24, 380). Mercurous and mercuric iodide, mercurous and mercuric chloride, antimony tri-iodide, and bismuth trichloride show well-marked effects after exposure for some time to the ultra violet rays, but dry zinc chloride and phosphoric oxide appear to be inactive. The action is very small in the case of lead iodide and almost negligible for ferric chloride. Although large and gradually increasing effects are obtained with the above-mentioned halogen salts, the initial photo-electric activity of these substances is either zero or very small, except in the case of antimony tri-iodide. From the observed behavior, it appears that the salts themselves are not photo-electric for light of the wave-length employed, and that the emission of electrons is due to the primary decomposition of the halogen salt by the light and the subsequent action of the rays on the separated metal. The more stable the salt, the less is the effect produced. Although zinc chloride and phosphoric oxide are inactive when dry, they show a distinct effect in contact with moist air. This cannot be accounted for by the photo-electric activity of water.

Experiments with anthracene show that the photo-electric activity of this substance is produced entirely by light of wave-length shorter than $\lambda = 2002$. The maximum emission velocity for $\lambda = 1849$ is 0.87 volt.

Experiments by *Pohl* (Ber. Deut. physikal Ges., 1909, 715) with an alloy of potassium and sodium and ultra violet radiation of short wave-length show that the photo-electric behavior of the alkali metals in polarized light is the same as that observed in the case of other metals.

Variations of the Temperature-coefficients of Photochemical Reactions

Padoa and *Minganti* (Atti. R. Accad. Lincei, 1915 (v), 24, ii, 97; J. Chem. Soc., 1915, Abs. *108*, ii, 719) have measured the temperature-coefficients of Eder's reaction,

$2HgCl_2 + (NH_4)_2C_2O_4 = 2HgCl + 2NH_4Cl + 2CO_2$, proceeding under the influence of lights of various wave-lengths. Besides white light, ultra violet light, with the luminous zone $\lambda = 400$ 280, and maximum, intensity at 366, dark blue with the zone $\lambda = 478$ — 410 and the maximum at 366, and the green with the zone $\lambda = 540$—505 and the maximum at $\lambda = 533$, were used. In the case of the green light, the reaction proceeds so slowly that a little dilute aqueous tetrachromofluorescin was added as a sensitizer; the latter was also employed in some of the experiments with white light.

For the temperature interval 20-40°, the temperature coefficients are as follows: white light, 1.29; ultra violet 1.05, dark blue, 1.21; green, with sensitizer, 1.75; white with sensitizer, 1.50. In accordance with the results previously obtained with phototropic substances, the temperature-coefficients increase with the wave-length of the activating light. With white light, the sensitizer used raises the temperature-coefficient considerably, since it gives preponderance to the action of the yellow and green rays, which without it are of slight activity. Red light has no action even in presence of a sensitizer.

Certain evidence indicates that, in the assimilatory process of plants under the influence of chlorophyll, the temperature-coefficient is considerably greater than 1.

Chemical Action of Light Contrasted with that of the Silent Electric Discharge

Berthelot (Ann. Chim. Phys., 1900 (vii), 19, 150) found benzene to remain unaltered when exposed to bright sunlight for several months in sealed tubes containing hydrogen or argon, although it combined with oxygen, yielding resinous products; if placed over mercury, a brown sediment, which is derived from the thiophene present in the hydrocarbon, forms at the junction of the liquids. Carbon disulphide, under these conditions, undergoes a partial decomposition, and the sides of the containing vessel become coated with a brown deposit; when exposed to diffused light, it remains unaltered, and does not react with hydrogen or argon. When a mixture of argon and gaseous carbon disulphide is submitted to the action of the silent discharge for three months in diffused light, the electrodes being maintained at a difference of potential of 200 volts, the former gas remains unaltered, while 60 per cent. of the latter is converted into yellow, resinous products.

Reaction Nuclei as Catalyzers

Weigert (Ann. Physik., 1907 (iv), *24*, 243) observes that when gaseous systems containing chlorine are exposed to light, molecular complexes are probably produced, which act catalytically as reaction nuclei. At these nuclei, it may be supposed, equilibrium between the reacting gases is established with such rapidity that the further progress of the reaction is conditioned by the rate of diffusion to these nuclei of the remaining portions of the gases. According to this theory, therefore, photochemical reactions may be brought under the category of heterogeneous reactions. Experimental evidence is brought forward showing that when chlorine is exposed to ultra violet, violet, or blue light, the production of fog may be actually observed. If Weigert's view is correct, then reactions which are not themselves affected by light should be catalytically affected by the presence of the reaction nuclei already mentioned. In this connection, it is shown that the formation of water, the formation of sulphur trioxide, the dissociation of carbonyl chloride, the decomposition of ozone, the Deacon chlorine process, and the formation of ammonia from its elements are reactions which, although not themselves sensitive to light, may be sensitised by adding chlorine and exposing to light. The fact that all photochemical reactions known to Weigert were unimolecular, and that the temperature-coefficient of these reactions was of the same order as the temperature-coefficient of a diffusion process is regarded as lending support to the conception of photochemical reactions as heterogeneous catalytic reactions. That the activity of chlorine and other substances sensitive to light does not cease immediately when exposure is stopped is also in favor of the foregoing view that definite nuclei are produced.

Law of Mass Action

Hanssen (Compt. rend. 1907, 145, 564) asserts that many photochemical actions such as the decomposition of oxalic acid and hydrochloric acid and the union of carbon monoxide and chlorine, are subjected to the ordinary law of mass action. The action of a strong light on glucosides, like saponin and cyclamin; enzymes, like rennet and trypsin and on toxins and immune-serum impairs all of them, the action being largely due to the ultra violet rays. The weakening action proceeds regularly, and may be expressed by means of the ordinary equation for a uni-molecular reaction.

Luminescence

The luminescence produced by a number of substances under a series of conditions have been determined by *Farnau* (J. Physikal. Chem., 1913, *17*, 637; J. Chem. Soc., 1913, Abs. *104*, ii., 1001). The experiments include observations on the cathode-luminescence, canal ray luminescence, ultra violet luminescence, luminescence by heating, luminescence by trituration, chemiluminescence, and crystal-luminescence of a series of the haloids of sodium, potassium, cadmium, zinc, mercury, lithium, rubidium and caesium, together with, in a few cases, the carbonates and sulphates. Farnau draws the conclusion that luminescence of all kinds is due to a chemical reaction. Increase in the rate of the reaction, brought about either by a catalytic agent or by increase in the temperature, increases the luminescence. The nature of the luminescence is but slightly altered by the nature of the catalyst or the temperature change. The nature of the luminescence in most cases depends upon the metal of the salts, but in a few cases the acid radicle has an influence. The nature of the luminescence is the same no matter how it is produced.

Different Effects of Ultra Violet Light

From a summary of results obtained in the investigation of the action of ultra violet light on gases *Ransauer* (Ber. Deut. Physikal. Ges., 1911, *13*, 899; J. Chem. Soc. 1912, Abs. 102, ii, 5) concludes it is necessary to differentiate between (1) purely chemical action, (2) formation of fog nuclei, and (3) formation of carriers of electricity. Pure chemical changes, such as the transformation of oxygen into ozone, are brought about by light which is not at all readily absorbed. Such changes are quite independent of the formation of fog nuclei or ions. The formation of fog nuclei is also due to chemical action in the first instance, and only differs from changes of the first type in that the end-products are solid or liquid particles. These changes are also independent of the liberation of electrons. The third kind of action differs from the other two in that it is determined by ultra violet rays which are selectively absorbed. The rays which are mainly responsible for this type of change correspond with wave lengths in the extreme ultra violet region.

Variation in Wave-Lengths

Berthelot and *Gaudechon* (Compt. rend., 1912, *155*, 207) compare the effectiveness of different ultra violet rays in the photochemical synthesis of quaternary compounds in the polymerisation of different gases and in the photolysis of acetone. Equal volumes of carbon monoxide and ammonia combine in a few hours to give formamide under the influence of the ultra violet rays $\lambda < 0.2\ \mu$) from a mercury-quartz lamp. Combination also takes place slowly with medium ultra violet rays ($\lambda=0.2$ to $0.3\ \mu$), but there is no combination under the influence of initial ultra violet or solar rays ($\lambda < 0.3\ \mu$). On the other hand, formamide slowly decomposes when submitted to ultra violet rays, the reaction being complicated by dehydration and formation of hydrogen cyanide. Light, less markedly than heat, produces polymerisation (compare Compt. rend. 1910, *150*, 1164). Cyanogen exposed to sunlight slowly polymerises. Acetylene, under the same conditions, is not changed, but it too polymerises under the influence of the ultra violet rays from a mercury-quartz lamp. Acetone is rapidly decomposed into carbon monoxide and ethane by the rays from the lamp, but is not acted on by sunlight. A 10% aqueous solution of acetone behaves similarly, except that with sunlight the acetone is hydrated and decomposed, giving methane and acetic acid.

Berthelot and *Gaudechon* (Compt. rend. 1913, 156, 889) have studied the stability of the hydrogen compounds with the members of the chlorine and oxygen groups of elements towards light of different wavelength. As in the case of decomposition by heat, it holds good that, in the same family of elements, the stability of the hydrogen compounds with respect to light decreases as the atomic weight increases. Substances which are only dissociated at high temperatures are similarly only affected by the very rapid vibration of the extreme ultra violet light. Hydrogen chloride requires ultra violet light ($x < 0.2\ \mu$) for decomposition which even then is slow, while under similar conditions hydrogen bromide is rapidly and completely decomposed. Hydrogen iodide is decomposed by blue and violet light. A similar relationship is found in the case of water-vapor, hydrogen sulphide, selenide and telluride.

This rule holds good in the case of the nitrogen and carbon groups (Compt. rend., 1913, *156*, 1243; J. Chem. Soc. 1913, Abs. 104, ii., 458). Zinc ethyl is rapidly decomposed by the light from a quartz mercury lamp; carbonyl chloride is slowly decomposed by the extreme ultra violet rays, while sulphur hexafluoride is unaffected by the light from a mercury lamp.

Fluorescence as an Aid in Sterilizing Water

The use of fluorescent bodies to assist in the sterilization of water, particularly water rendered dull by humic substances, has been suggested. The Quartzlampen Ges. (British Patent 112,149, Dec. 6, 1916) recommend the addition to water which is to be exposed to the rays from a quartz burner, of a dye, color or fluorescent body. Suitable substances are eosin, rhodamines, fuchsin, methylene blue, Nile blue, phenazine, toluylene red, phenosafranine, fluoresceine, etrachloro-, tetrabromo-, tetraiodo-, tetrachlorotetrabromo-, tetrachloro-tetraiodofluoresceine, chloride of acridine, chrysophanic acid, phenylquinaldine, quinine, hydrastinine, chlorophyll, alcoholic extracts of green vegetables, and uranium or iron salts.

The flame of carbon disulphide burning in nitric oxide is shown by *Tassilly* and *Gambier* (Compt. rend. 1910, *151*, 342) to have a feeble sterilising action on water containing bacteria exposed to its light.

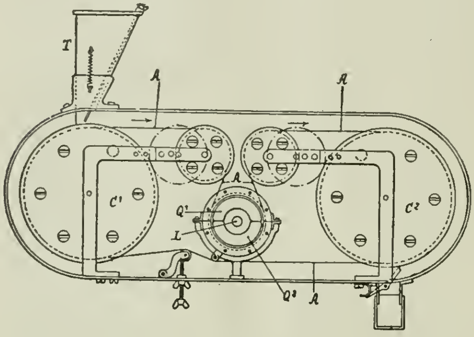

Fig. 4—Olivier's Apparatus for the Vulcanization of Rubber.

Tables of data on the chemical action of tropical sunlight obtained by *Fowler* (Mem. Manchester Phil. Soc., 1908, 52, xiv, 1; J. Chem. Soc. 1908, Abs. ii, *94*, 914) from measurements made in Calcutta and on the Mediterranean and Arabian Seas are recorded. The highest record corresponds with an actinic effect which is forty-two times as great as the lowest record obtained on a bright December day in Manchester. No relationship appears to exist between the photochemical and sun-stroke effect of sunlight. Solutions of bleaching powder lose their available chlorine with great rapidity on exposure to tropical sunlight. The effect is much more marked in the case of dilute solutions than it is in strong solutions.

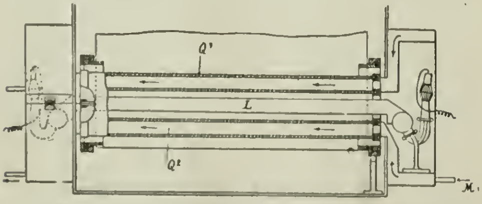

Fig. 5—Quartz Jacketed Lamp Used in Olivier's Apparatus Above.

Vulcanization of Rubber

The practical vulcanization of rubber by the ultra violet ray may be carried out with *Olivier's* apparatus (U. S. Patent 1,256,496, Feb. 12, 1918). Olivier notes that rubber vulcanized by means of ultra violet light is particularly useful for cementing purposes, since the treatment produces thick elastic liquids which are real liquid rubbers. With former cementing processes, the surfaces of rubber to be cemented were coated with a solution containing 6 to 12 per cent. of rubber and usually several layers of such cement were necessary to effect the cementing. With this method of producing the solution a much more dilute solution can be obtained than heretofore. In fact, the dilution may be 0.5 to 0.6 per cent. When this latter solution is used for cementing, the two rubber surfaces absorb the solution and, upon placing the surfaces in contact it is claimed that a real autogenous union of the two rubber surfaces can be obtained. When surfaces of rubber are so united, they are not separated by a comparatively thick layer of cement, as with former cements, but they are in immediate contact on account of the penetration due to the dilution of the solution.

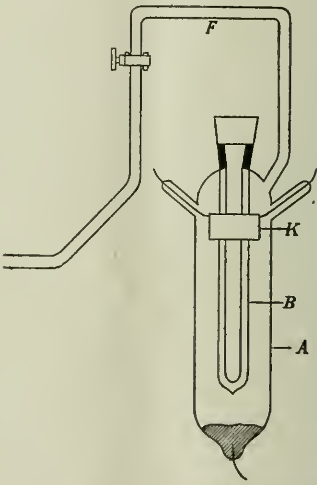

Fig. 6—Fischer's Mercury Arc Lamp for Formation of Ozone.

In carrying out the process, the first factor to be fixed is the duration of exposure to the ultra violet rays. Experience has shown that after a certain time of exposure, the decomposition of the rubber increases rapidly, whereas the vulcanization effect only increases to a small extent. The duration of exposure of course changes according to conditions, depending on the size lamp used, the thickness of the solution, and the distance of the solution from the lamp. When using a 220 volt, 3 ampere, quartz lamp and with a solution a fraction of a millimeter in thickness placed at a distance of 5 centimeters from the lamp, the duration limit would be forty seconds. When solutions of rubber are being vulcanized with ultra violet rays, the sulphur usually used can be replaced by sulphides and in a general way, by any sulphides which can be decomposed by ultra violet rays, such as carbon disulphide, allyl sulphide or antimony sulphide. After vulcanization, when these sulphides are used, there is no uncombined sulphur left in the solution as, according to Olivier, it is precisely the sulphur which is decomposed out of the sulphides which allies itself with the rubber. Vulcanization can also by effected by adding at the same time to the solution, ordinary free sulphur and carbon disulphide. Under these conditions, vulcanization occurs concurrently between the rubber and the sulphur decomposed out of the sulphide.

The apparatus is shown in *Fig. 4*, in which C^1 and C^2 are two cylinders, supported in a housing having a hopper T for the introduction of the rubber solution. L is an ultra violet lamp and A is an endless belt which passes about the lower part of the lamp, around the cylinders C^1 and C^2 and over two rollers placed above the lamp. The rubber solution is carried by the belt from the supply hopper T around the lamp, where vulcanization takes place and the vulcanized product is removed by the scraper N. The burner is kept cool by water jackets Q^1 and Q^2, which are made of quartz.

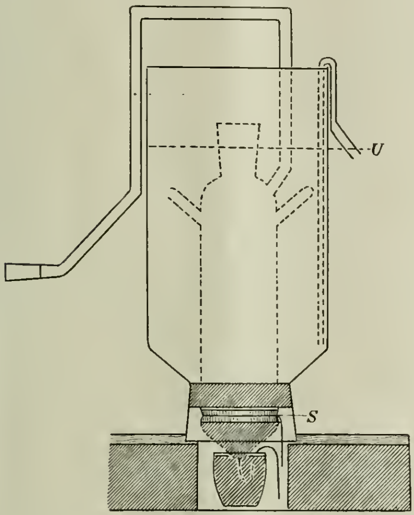

Fig. 7—Detail of Fischer's Lamp, Showing Tin Foil Ring.

The lamp L with quartz jackets Q^1 and Q^2 is shown in *Fig. 5*. The housing of the lamp is mounted on brackets so the lamp may be rocked in starting. Water is admitted to the jackets by the pipe M.

The Fluorometer

An instrument is described by *Winther*, (Zeitsch. Elektrochem., 1913, *19*, 389; J. Chem. Soc. 1913, Abs. *104*, ii, 458) termed a fluorometer, by means of which the energy of a ray of given wave-length can be measured irrespective of the presence of ultra red rays The principle involved consists in allowing a beam of light from a normal lamp, after passing through light filters, to enter a rectangular quartz vessel, which is filled with a fluorescent material. In this way a narrow, fluorescent beam is produced in the vessel. A second beam is produced parallel with and a few millimeters removed from the first beam, by the light under investigation. This second beam enters at the opposite side of the vessel. By means of a lens and cross wire moving over a graduated scale, the position of equal brightness is measured. The fluorescent solutions employed by Winther are: (1) Rhodamine-B, made up of 0.004 gram per litre, useful for wavelengths 600 to 460 $\mu\mu$, and can be used for the ultra violet from 340 $\mu\mu$ and downwards. (2) Sodium flourescein, made up of 0.01 gram per litre + 2.50 cc. of N-sodium hydroxide, useful for wave lengths from 520 $\mu\mu$ down to 254 $\mu\mu$. (3) Quinine sulphate, made up of 0.1 gram per litre + 4 cc. N-sulphuric acid, useful down to 260 $\mu\mu$. In addition to its uses for the measurement of energy values, the fluorometer is serviceable in measuring absorption curves, and also the reaction velocities of light-sensitive and non-sensitive systems. A number of light filters for various regions are described by Winther, and a criticism of many of the older light filters is given.

Fischer Ultra Violet Lamp

Fischer (Ber., 1905, 2630) constructed a mercury arc lamp with quartz jacket suitable for chemical purposes which he used in experiments on the formation of ozone. This consists of an exhausted double-walled

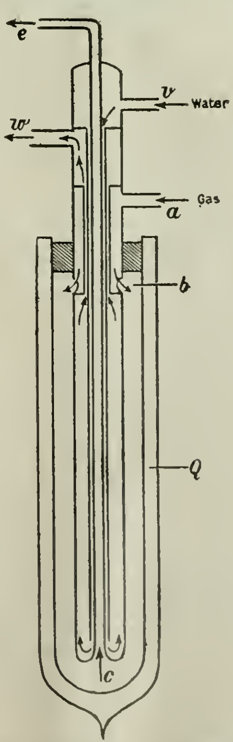

Fig. 8—Method Employed for Internal Cooling of Fischer Lamp.

quartz cylinder B (*Fig. 6*) fixed with sealing-wax into the neck of a surrounding cylindrical glass vessel A, connected with an air pump by the tube F. The anode consists of an iron ring K, which surrounds the quartz cylinder and is suspended by means of two platinum wires fused into the walls of the glass vessel. Mercury is placed in the bottom of the latter to serve as cathode. Near the bottom of the glass vessel is an outer ring, S, of tin foil (*Fig. 7*), connected with a copper wire so that an induction coil may be used for lighting. The glass vessel dips into a small mercury trough into which the current is led. The lamp is operated at 20 volts and 5 amperes. Arrangements are made to cool the lamp both internally and externally, so that the temperature in the interior of the lamp is kept down, thus maintaining a low density of the mercury vapor, and favoring the formation of ultra violet light. External cooling is accomplished by a water jacket shown in *Fig. 7* having the water level at U, while the internal cooling device is shown in *Fig. 8*. The latter is placed in the double-walled quartz vessel Q. Water enters v and leaves by w. When exposing gases to the light, these may be admitted at a, pass into the quartz vessel at b, flowing downwardly to c, where they move upwardly to the exit e.

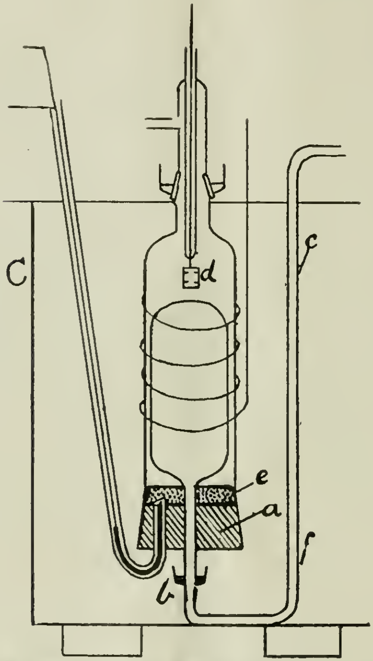

Fig. 9—Chapman, Chadwick and Ramsbottom's Lamp for Treating Gases.

Lamps for Treating Gases

The exposure of gases to ultra violet light was carried out by *Chapman, Chadwick* and *Ramsbottom* (J. Chem. Soc. Trans. 1907, *91*, 945) in apparatus of the form shown in *Fig. 9*. A bulb of quartz, in which the gases are placed that are to be exposed to the light, is enclosed in a glass mercury lamp of which the cathode is a pool of mercury and the anode a short cylinder of iron suspended in the upper part of the glass container. The latter is exhausted by means of a Sprengel pump. The quartz bulb has an outlet tube passing through the bottom of the lamp and communicating with a pump. The lamp is operated on a current of 6 amperes.

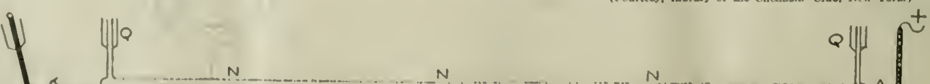
Fig. 10—Coehn and Becker's Lamp for the Oxidation of SO_2.

An apparatus recommended by *Coehn* and *Becker* (Zeitsch. f. physik. Chem., 1910, *70*, 90; Zeitsch. f. Elektrochem. 1907, *13*, 545) for photochemical work and used by them in the oxidation of sulphur dioxide is shown in *Fig. 10*.

The lamp consists of a glass vessel IV in which the double-walled quartz vessel II and III is placed. A mercury seal is used at the top of the vessel IV. The lamp is placed in a water-jacket or cooling vessel V. In order to make the burning uniform a magnet M is placed in a glass tube in the lamp as shown. A

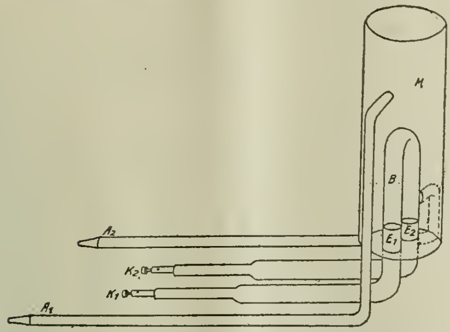
Fig. 11—Burner for Technical Applications of Photochemistry.

(Courtesy, Library of the Chemists' Club, New York.)



quartz tube I is inserted in the vessel II through which gases may be passed by means of the inlet and outlet tubes G.

A burner for technical applications of photochemistry is shown in *Fig. 11.*



(Courtesy, Library of the Chemists' Club, New York.)

Fig. 12—Weigert's Burner for Treatment of Gases.

A quartz lamp K L A has a length of 115 cm. The light zone is maintained in the tube L, 1.8 cm. in diameter. A tube R, 5 cm. in diameter and 100 cm. in length, is fused on the tube L.

Reaction mixtures are passed in and out by the openings Q, Q. The tube R is wound with nickel wire and jacketed with asbestos. The temperature is determined by thermo elements at N.

A quartz-jacketed burner used by *Weigert* (Zeitsch. f. physik. Chem. 1912, *80,* 69) especially for exposure of gases to ultra violet rays has the form shown in *Fig. 12.*

A mercury arc is formed in the inverted U tube B, between the surfaces of mercury E$_1$, and E$_2$, electrical connection being made at K$_1$ and K$_2$. M is a mantle of thin quartz enclosing the burner. Capillary tubes of Quartz, A$_1$ and A$_2$, are used for changing the gaseous atmosphere in the space about the burner. The apparatus is mounted in a watertight casing G shown in *Fig. 13.* Q is a quartz plate serving as a window for external exposures. V is an arrangement which enables the apparatus to be made gas tight.

A "Home-Made" Ultra Violet Lamp

At the time when there were no quartz mercury-vapor lamps on the market in this country *Bovie* (J. Biol. Chem. 1915, 315) (Laboratory of Plant Physiology, Harvard University) required a source of ultra violet light for certain biological and photochemical investigations. He constructed quartz lamps which he states are less expensive than any of the commercial lamps known to him and which after 4 years of use still give excellent results. The lamps are not difficult to make and the design of this "home-made" apparatus can be altered to suit particular requirements. The quartz must be worked in an oxyhydrogen flame, and the burner must be adjusted so as to give the highest temperature possible; but the technique required for shaping the lamps is simpler than that required to make an ordinary T-joint in glass tubing, since the quartz joints do not have to be annealed. A good vacuum pump is required for exhausting the lamp. The greatest difficulty is found in making the seals at the points where the electrodes enter. The literature contains a number of more or less complicated and impractical methods, but the seals described below are easily made and are efficient.

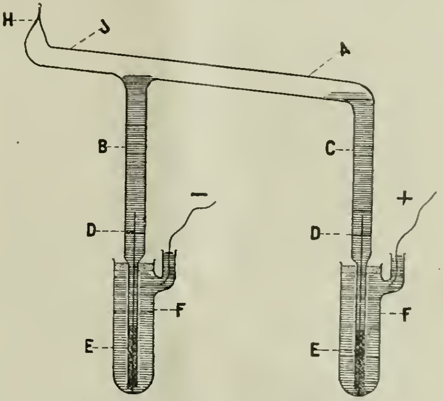

Fig. 14—Bovie's "Home-Made" Quartz Lamp.

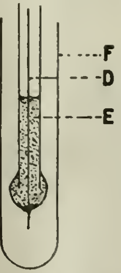

Fig. 15—Bovie's Apparatus, Detail of Seal.

Fig. 14 shows a simple form which the lamp may take.[1] A is a quartz tube 1 cm. in diameter. One end is bent downward to form the positive electrode C. A quartz tube of the same diameter is sealed in, near the other end, to form the negative electrode B. The distance between B and C is about 10 cm. The end of the tube A forms a condenser. The lamp is sealed, after exhausting at H. The tube A should be inclined to the horizontal position at an angle of 6° to 7°, the end J being higher, so that the condensed mercury will flow back into C. Pieces of 5 mm. quartz tubing are sealed to the lower ends of B and C. These in turn are set in mercury cisterns F, F (made of glass); test-tubes may be used. The small tubes are sealed at E with De Khotinsky cement.[2] The detail of the seal is shown in *Fig. 15*. The bulb of wax on the outside is necessary in order to make the seal air-tight. The iron wire D conducts the electric current through the wax seal. The mercury cisterns F, F radiate heat and also make the seal at E more secure by furnishing an additional mercury seal.

During the process of pumping the lamp should be turned, to allow the mercury to flow out of B and C, so as to free any imprisoned air bubbles. The lamp should then be placed in an upright position and the mercury in the upper parts of B and C boiled vigorously, keeping the wax at E cool by having the lamp stand in a dish of water. Lastly, the lamp should be connected with a 110 volt direct current (with suitable resistance in series with it), and run for one or two hours. When it appears to run evenly the vacuum pump should be stopped, and the lamp sealed off at H. The tube A should be drawn down to a small diameter at this point before the pumping begins.

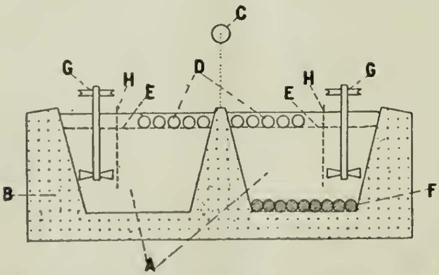

Fig. 16—Bovie; Arrangement of Apparatus for Experiment in Photochemistry.

The lamp should be used on a 110 volt direct current with 5 or 6 sixteen candle power bulbs in multiple as resistance. The lamp will carry from 1.25 to 1.5 amperes, depending upon the amount of cooling at the electrodes B and C. When convenient it is desirable to arrange the experiments so that the lamp can stand in a dish of water, with the water surface well up on B and C. The lamp is started by tipping, or a Bunsen flame may be directed upon the surface of the electrode C. When the mercury boils the arc will start. As the lamp is made of quartz there need be no fear of breaking by sudden heating or cooling.

The tube A between B and C should be made of transparent quartz, but all other parts can be made of the cheaper translucent, fused silica. A lamp made for physical experiments, where only a small beam of ultra violet light was needed, was made entirely of fused silica, save for a small space between B and C, about 1 cm. long, where a small piece of transparent quartz was inserted.

Fig. 16 shows a convenient arrangement for an experiment in photochemistry. The drawing shows a cross-section of the lamp, baths, tubes, etc., as used by Bovie in studying the temperature-coefficient of the coagulation of egg-albumin by ultra violet light. A, A are copper trays set in the insulating case B. C is the lamp. The quartz test-tubes which hold the albumin are supported at D by the shelves of E, E. The water in one of the trays is heated by the electric heating coil F, while the water in the other tray is kept at 0°, by placing chopped ice below the shelf E. The electric current in the heating coil is controlled by a thermoregulator. G, G are stirrers. The partitions H, H serve to prevent the stirrers from disturbing the surface of the water, and thus causing irregular variations in the reflection of light at the surface of the water. In this experiment the mercury cisterns (shown at F, F in Figure 1) stood in the ice water bath.

Fig. 17 shows another of the possible forms of the lamp. It will be seen that the tube A is vertical. The electrode C, which is left open at the bottom, dips into a cistern of mercury M. This lamp was designed to run on a 220 volt circuit, and the distance between B and C is 30 cm. The lamp, however, will work as well on a 110 volt circuit; for, as will be seen presently, the distance between C and B is easily adjusted. The arc is started in this lamp by elevating the mercury cistern M until the mercury in C comes in contact with that in B. The distance between the surface of the mercury in M and the surface in C is equal to the height of the barometric column, since the surface at M is exposed to the air. When the lamp is running on a 110 volt circuit the arc is not stretched down as far as when running on 220 volts. In place of the mercury cistern M, one can use a smaller chamber closed at the top, with the air space above the mercury connected with a water aspirator. The height of the mercury in C can then be controlled by varying the air pressure above the mercury in the cistern. With this arrangement the distance between M and C may be shorter. An air trap L is inserted between M and C to prevent the accidental entrance of air bubbles into A.

It will be noticed that the condenser J is not in a line with A, but is a little to one side. This is important, for a certain amount (about half) of the condensed mercury must be returned to the electrode

---

[1] The form of this lamp is copied from a lamp made by Dr. C. A. Kraus.

[2] This cement may be obtained from A. De Khotinsky, [illegible] Drexel Avenue, Chicago, Ill.

B, else it will boil dry. The condenser J and the electrode B are provided with copper radiators, K. (The radiators were taken from discarded Nernst lamps.) By using these radiators the lamp could be made to carry a current of four amperes. With this current density and with an arc 30 cm. long the lamp emits such an abundance of ultra violet light that the air in the room is quickly filled with ozone. The photochemical power of the lamp may perhaps best be judged from the fact that an exposure of one or two minutes at a distance of one meter will produce such a "sunburn" as to cause the skin to peel.

A More Powerful Burner

A more powerful lamp is described by *Bovie* (J. Am. Chem. Soc. 1915, 1721) who states that the improved lamp is so simple, efficient and durable that the employment of ultra violet light in biological and chemical investigations should be decidedly facilitated by its use.

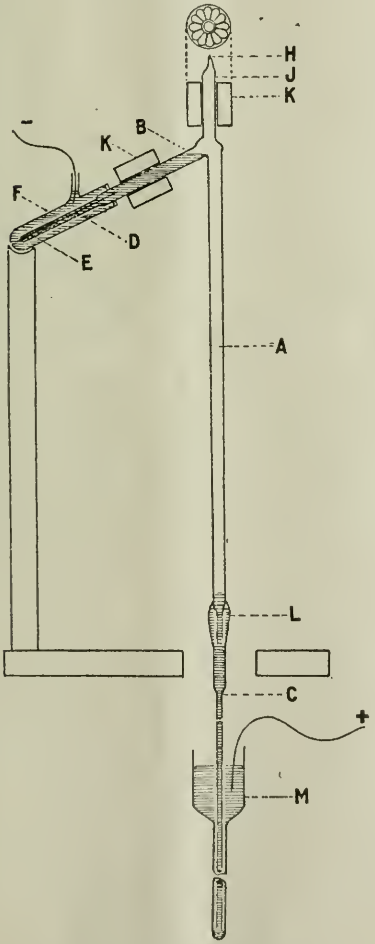

Fig. 17—Bovie; Another Form of "Home-Made" Apparatus.

The principles of the mercury air-pump have been incorporated into the design so that no pump, other than an ordinary water aspirator, is required to exhaust the lamp to a very high vacuum. This feature not only does away with all troubles connected with the original exhaustion of the lamp, but makes it possible to re-exhaust the lamp quickly and easily at any time. The lamp can be re-exhausted without in any way disturbing the chemical substances under investigation and without interrupting the exposure for more than a fraction of a minute. The length of life of the lamp is, therefore, limited only by the durability of the quartz. A maximum of efficiency is obtained by constructing the apparatus so that the exposed substance receives practically all of the light given out. The temperature of the substance which is being investigated is at all times under the control of the operator.

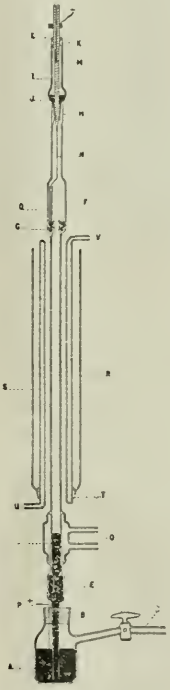

Fig. 18—Details of a More Powerful Form of Lamp Constructed by Bovie.

The lamp consists of a transparent quartz tube, 70 cm. in length, closed at one end with a stopper of invar and inverted in a cistern containing pure mercury. The mercury cistern (A), *Fig. 18*, is closed at the top by a rubber stopper B through which the quartz tube passes. The air pressure in the cistern A may be varied by admitting or removing air through the side tube C. The height of the mercury column D varies with the air pressure in A. The quartz tube is of 7 mm. internal diameter, for the greater part of its length. It is enlarged at E to form an air-trap, also at F to form a condensation chamber, and again at J to form a reservoir for a mercury seal. The construction of the air-trap E will be understood from the drawing. Immediately above the air trap is a water-jacket, O. Water circulating through this jacket serves to keep the positive electrode cool. This makes it possible to greatly increase the current density of the arc. The condensation-chamber F has at its lower end an internal flange which, together with the wall of the chamber, forms a pocket to hold a ring of mercury G which forms the negative electrode of the lamp. The wall of the tube is thickened at H and is ground to receive the conical end of the invar stopper I. This ground joint is sealed with mercury at J. The top of the quartz tube at K is constructed so as to fit closely about the upper part of the invar stopper. The joint here is made practically air-tight by a ring of soft, rubber gum, L. This construction of the joint at K makes it possible to slightly raise or lower the invar stopper without destroying the seal at J. A small hole extends along the axis of the upper part of the invar stopper and opens at M into the space between the joint K and the mercury seal J.

The invar stopper has electrical connections with the mercury ring G by the soft iron wire N. It is essential that the lower end of the iron wire N terminate in a ring which dips well beneath the surface of the mercury. Otherwise when heavy currents are passed through the lamp and the mercury ring G contracts, due to the so-called "pinch-phenomenon," the end of the iron wire will be exposed and will be melted off because of the intense heat of the arc which will thus be formed between it and the mercury ring G. The lower part of the wire is further protected by a small quartz tube Q, the lower end of which dips beneath the surface of the mercury. Without the protection of the quartz tube Q the wire itself, instead of the mercury ring G, will become the negative electrode and the heat thus developed will cause the wire to melt.

The condensation chamber F is cooled by a copper radiator, or better by an air-blast.

The upper surface of the mercury column D serves as the positive electrode of the lamp. The current is conducted to it through the iron wire P which passes out through the rubber stopper B.

The lamp is evacuated as follows: The top of the invar stopper is connected by means of a rubber tube to the water aspirator. The stopper is lifted slightly so as to leave an opening at the ground joint H and the aspirator is started. The air is thus drawn out from the body of the tube. The stopcock C is opened and as the quartz tube is evacuated, the mercury column D rises. The pumping is continued until the mercury column reaches and passes the ground joint at H. The stopper is then pressed down so that the joint is closed. The mercury which has passed above the joint serves as an air-tight seal.

The tube C is now connected with an aspirator and the air pressure in the cistern is reduced. The mercury column falls, leaving a Torricellian vacuum in the space below the invar stopper. In order to remove the last traces of air from the lamp it is necessary to boil the mercury column D during the first pumping, and in order to insure an air-tight seal at H the mercury in J must be boiled each time the seal is made. The occluded gases which are usually contained in the iron wire N and which are driven out during the first few "burning hours" of a new lamp, are removed from time to time by allowing the mercury column D to rise past the joint H. After these gases have been removed, the lamp seldom needs to be repumped. After pumping, the aspirator is disconnected from the invar stopper I, leaving the space above the mercury at J open to the outside air.

The invar stopper should not be heated while it is seated in the grinding at H. There is sufficient expansion of the invar at high temperatures to break the quartz. As long as the partial vacuum is maintained in the space above J, the stopper may be held up out of its seat wtihout losing the mercury seal. The stopper is seated only when the lamp has cooled. It will be understood that the Bunsen flame may be turned directly on the quartz without fear of breaking. After heating the lamp is cooled immediately by a dash of cold water.

The lamp is operated on a direct current in series with a resistance, which, for voltages above 110, should be variable. It carries a current of from 12 to 15 amperes. The maximum length of arc obtainable is dependent upon the voltage of the line upon which the lamp is operated. With 110 volts on the line, an arc of about 9 inches can be maintained. With 220 volts, the lamp burns with an arc over 2 feet long. It is essential that the mercury column D be made the positive electrode; the lamp will not burn if the poles are reversed.

The solutions to be exposed to the light are contained in the triple walled beaker R. The outside wall of the beaker is made of glass. The inside S is a screen for absorbing the heat rays. It is a double-walled quartz tube with the space between the walls open to the outside through the small tubes U and V. The heat rays are absorbed by a stream of water which passes between the walls of the tube. By adding various substances to the water, the double-walled quartz tube may be used as a selective light filter, or if desired, it may be used as a chamber in which to expose gases. The outside wall of the beaker is joined at T to the inner part by a rubber ring which forms the bottom of the beaker. Rubber is very unstable under the action of ultra violet light, and it would be better to have a ground joint at T, but the quartz tube used by Bovie was too thin to stand grinding. The beaker has a capacity of 100 cc.

For measuring the temperature and stirring the solution during the exposure, a device is employed which is not shown in the drawing. It consists of a hollow gold wire (size No. 14 Brown and Sharp gage), bearing two rings of gold which encircle the inside wall of the beaker. The device is given a slow up-and-down motion by a crank on a driving motor. The upright hollow gold wire extends above the beaker and is open at the top, so as to receive one of a pair of thermal junctions made up of No. 32 "Ideal" and copper wires. The other (constant) junction is placed in water in a Dewar flask which is provided with a thermometer. The variable junction is pushed well down inside the hollow gold wire. The free ends of the copper wires are connected with a galvanometer which is sufficiently sensitive so that differences in the temperatures of the two junctions can be read to 0.1°.

The lamp is operated as follows: The line wire is disconnected from the invar stopper I. The beaker R is slipped off over the top of the lamp, and, if necessary, its outer and inner parts are separated at the joint T, so that the surface of the inner part S can be cleaned. The beaker and line wire are now replaced. The variable resistance is set so that when the lamp is short-circuited it will carry between one and two amperes. The stream of water is now started through the water-jacket O. Air is admitted into the cistern A, causing the mercury column D to rise until electrical contact is made with the electrode G. The air pressure in the cistern A is now reduced, and the mercury column falls, stretching out the arc between D and G. The variable resistance is now adjusted so that the lamp carries the desired number of amperes. The current may be varied from less than one ampere to the full carrying capacity of the lamp.

Connections are now made at U and V, water is allowed to flow through the space between the walls of the tube S, and the solutions to be exposed are placed in the beaker.

Fig. 19 is from a photograph of the lamp as installed in the Biophysical Laboratory of the Cancer Commissoin of the Harvard Medical School. The lamp is inclosed in a metal case made from a brass tube 6 inches in diameter. It passes through a hole in the table (the mercury cistern A, *Fig. 18,* resting on the shelf below) and is held in an upright position by a light framework which is attached to the case near the top. The brass tube, forming the case, is split longitudinally into halves which are hinged together along one side. One-half only is fixed to the table, the other movable half forming a door. The tube can thus be opened, making all of the lamp accessible.

(To be continued in the August issue.)

Munson Now With Du Pont.

Louis S. Munson, for eleven years chemist for the Ault & Wiborg Co., Cincinnati, Ohio, has resigned to take charge of the production department of the new Du Point Dye Works at Wilmington, Del.

Fourth Chemical Exposition Will Show Progress

The fourth national exposition of chemical industries will be held in the Grand Central Palace, New York, during the week of September 23rd this year, its advisory committee composed of Charles H. Herty, chairman, Raymond F. Bacon, L. H. Baekeland, Ellwood Hendrick, Henry B. Faber, Bernard C. Hesse, A. D. Little, Wm. H. Nichols, R. P. Perry, H. C. Parmelee, G. W. Thompson, F. J. Tone, T. B. Wagner and M. C. Whitaker. Dr. Bacon of this committee is now head of the Chemical Warfare Section of the National Army and a member of General Pershing's staff.

The coming Exposition will be the largest Chemical Exposition ever held and it will be necessary to use three floors of the Grand Central Palace. The exposition is a war time necessity and regarding it as such each exhibitor is planning his exhibit that it will be of the greatest benefit to the country through the men who visit it all of whom are bent upon a serious purpose—that of producing war materials in large quantities, and constantly increasing this production till the war has been won by the United States and its allies.

The amount of floor space already engaged is greater than last year, the exhibits will be much more attractive, and a movement is under way to show all exhibits of machinery in operation under actual working conditions as they would be found in the field. The products of the chemicals manufactured and as they enter into the world's commerce will be there as examples of what the chemist has produced in America since the world war began.

The South is again sending exhibits from some sections, and Canada, too, is taking the opportunity of presenting the materials it has available for development by the chemist and financier. The Technical and business men all over the country should give heed to these exhibits, since they will show how they can meet the war time need. A section for the glass and ceramic industry has been added, with which the American Ceramic Society is co-operating.

The program for the exposition is in active preparation and will be a series of symposiums on the "Development of Chemical Industries in the United States, notably since July, 1914." This will embrace the period since the beginning of the European war, which, because of its removing the source of supply for our domestic industries, inspired the development of our own chemical industries that, now, when we ourselves have entered the war, are proving so efficient.

The program of motion pictures carries forward the idea of the symposiums, and pictures will be shown of the industries that have developed in so far as they can be with propriety.

The Use of Gas

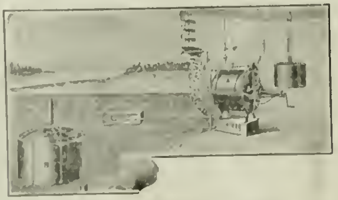
(Concluded from page 286.)

American Sugar Refining Co.; Borden's Condensed Milk Co.; U. S. Rubber Co., and thousands of other factories, homes, stores and large country estates.

Safety

It is worthy of note that never, since the first Tirrill gas machine was made in 1864, has there been an explosion. In fact, it is impossible for an explosion to occur, as one of the chief, exclusive features of the Tirrill "Equalizing" gas machine is that the gasoline is mixed outside of the building, underground and thirty feet away from it. No gas is ever made inside of the building—hence the absolute safety of the machine.

It is for this reason, as well as others, that this machine has the highest approval of the National Board of Fire Underwriters, who have listed it as standard Class A. Insurance rates are never affected by the installation of a Tirrill machine.



A Tirrill Machine Installed

Thus Tirrill "Equalizing" gas machines provide one of the cheapest, most satisfactory and convenient light and heat plants for every possible purpose. For economy of operation, safety, simplicity and duralibility, it is unexcelled. Under all conditions, a standard, uniform, non-poisonous gas is automatically delivered as wanted and no more.

It is perfectly simple and works like a clock; absolutely noiseless in operation. It has no delicate mechanism or complicated parts to get out of order; therefore no expense for repairs.

Furthermore, it is a permanent investment—not an expense. The plant is bought outright for cash or on convenient terms. There are no monthly bills to meet. Machines are made to last a lifetime.

The machine is never affected by weather conditions. It is a finished factory product and positively a most dependable cold-process gas machine. With the blue print and instructions furnished with every machine, any ordinary gas-fitter can easily set the machine up and a novice can operate it.

Economy

From hundreds of actual records, which can be shown, it is found that an average family, using a 25-light Tirrill "Equalizing" gas machine for illuminating, cooking and heating, will not spend more than $18 per year for this purpose.

The gas supplied by the Tirrill machine is even cheaper and better than some city gas. About three gallons of gasoline are used to make 1,000 cubic feet of gas.

Practically every one acknowledges that the brilliantly lighted city home is more attractive in every way than the dimly lighted house. Evening is the real home time. The city man has artificial light provided for him without work, without delay, without trouble, and without danger. Big corporations furnish him with bright light for every room in his house and heat for cooking and warming cold rooms.

This is considered absolutely necessary by him for his comfort and convenience and that of his family. Under no circumstances would he be without it. The price he pays for it is high, yet he believes he gets big value for his money—and he does.

In most city homes coal stoves and coal ranges are no longer in use for cooking and heating rooms. People have become tired of the never-ending care, dirt and ashes; the time and labor necessary to start the fire and keep it going.

In its place for cooking is found a gas range, which supplies heat only as desired, and which is lighted simply by striking a match and turning a key. Any desired degree of heat can be obtained, with practically no effort and which always cooks fast or slow, with the smallest amount of expense and attention.

In city homes, supplied by gas, you do not find some of the rooms shut off in the winter time, as it is so simple, economical and convenient to have every room warm and cozy and the whole house homelike and comfortable.

In a few minutes' time sufficient hot water is ready for dish washing, laundry work, baths, shaving and the many other uses for which hot water is desired.

The Tirrill "Equalizing" Gas Machine is made in standard sizes, according to requirements; price being according to size.

COAL-TAR CHEMISTRY SECTION

The Manufacture of Naphthols

[The current methods of producing the two naphthols are given in some fullness in a recent issue of *La Revue Des Products Chimiques*. The following translation appeared in *The Dyer and Calico Printer* for December 1, and will be of interest to many now utilizing napthalene derivatives on a large scale. The fact that this class of compounds is not represented in the group of high explosives and that the American output is rapidly increasing leads color manufacturers to employ napthalene derivatives as far as possible in enlarging their plans for new production.—Ed.]

Manufacture of B-Naphthol

The formation of b-naphthol is produced by a reaction similar to that yielding phenol, fusion of the the b-naphthalene sulfonate of sodium with caustic alkali:—

$$C_{10}H_7SO_3Na + 2\,NaOH = C_{10}H_7ONa + Na_2SO_3 + H_2O.$$

According to the temperature of the sulfonation of naphthalene, either the alpha or the beta derivative may be produced. At a low temperature the product is principally the alpha derivative, at a high temperature it is chiefly beta. It is not possible to procure the beta derivative absolutely free from the alpha isomer, and this has to be taken into account in the manufacture of b-napthol. The alpha-sulfonate must first be eliminated, as its presence lowers the value of the final product.

The manufacture of b-naphthol comprises, therefore, three principal operations:—

1. Sulfonation of naphthalene under conditions to obtain the maximum yield of beta-sulfonate.
2. Fusion of the naphthalene sulfonate of sodium with caustic soda.
3. Separation of the b-naphthol and its purification.

The sulfonation is carried out in a kier which can be heated to 200° C., either over the fire or with superheated steam, and the stirrer is kept energetically at work. The kier is charged with 100 kilos of sulfuric acid of 66° Bé, and 100 kilos of finely ground naphthalene are added, the contents being kept above the melting point of naphthalene, 79° C., so that it is melted.

When all the naphthalene has been put in, the temperature is raised to 160° C. and kept thus for three hours, the stirrer being kept going continuously. Then the temperature is raised to 170° C. for an hour and after this to 180° C. for the same period. Water and naphthalene distil over and are collected, from 3 to 4 kilos of naphthalene being recovered. Control samples are taken. The product should be very soluble in water and alkali, and when this period is reached the sulfonation is terminated.

The contents of the kier are run into 2,500 litres of water, and heated with 50 to 60 kilos of lime until the reaction is alkaline. The sulfate of lime formed is separated by filtration and the calcium salt in the filtrate is decomposed with the necessary quantity of carbonate of sodium, about 40 kilos, and concentrated by crystalization.

The sodium salt of b-sulfonic acid separates out and the alpha derivative, being more soluble and in smaller quantity, remains in the mother liquor.

It is a simpler matter, however, to separate out the b-naphthalene-sulfonate of sodium, without the use of lime. For this purpose, the contents of the kier are run as before into 2,500 litres of water and salted with sea salt or sulfate of sodium, or neutralized partially by the addition of about 40 kilos of carbonate of sodium. The sodium salt thus precipitated is filtered in the press and then dried in a vacuum. The yield is from 160 to 165 kilos.

Fusion With Alkali

The general recommendation is to take two parts of caustic soda for one part of sodium naphthalene-sulfonate. This proportion is excessive and makes the process expensive; theoretically, 80 parts of soda are sufficient for 250 parts of sulfonate.

The fusion is effected in a semi-spherical basin furnished with a stirrer. To commence with, 100 kilos of caustic soda are melted in 20 litres of water, the temperature is raised to 200° C. and 160 kilos of naphthaiene-sulfonate of sodium are introduced gradually. The temperature is then raised to 300° C. The fusion is finished in five or six hours. The very liquid mass is run into 2,000 litres of water, and sufficient hydrochloric acid is added to set the naphthol at liberty without decomposing the sulfite of sodium. The b-naphthol is filtered in the press and purified by vacuum distillation. This gives a very pure product. A residue remains which is very rich in tar, about 10% to 15% of the weight of the naphthol.

According to an Agfa patent a very pure b-naphthol, free from the oxidation products formed by fusion in an open vessel, is obtained by fusion under pressure in an autoclave. The autoclave is charged with 46 parts of b-naphthalene sulfonate of sodium and 50 parts of caustic soda solution at 40° Bé., and heated from ten to twenty hours at 300° to 330° C. The b-naphthol is separated as already described.

B-naphthol is usually sold in pieces or in powder. It melts in a pure state, at 123° C., and distils at 285°-286° C., slightly decomposing.

The cost of production in France is estimated at 80 to 85 francs the 100 kilos. With cheaper raw materials, the German works can produce it at 70 francs and can compete in France, in spite of the 15 francs per 100 kilos duty.

The sale price was 110 francs per 100 kilos before the war. B-naphthol was sold at 16 francs per kilo in 1916, and there is now a considerable margin between the cost and the sale price.

B-naphthol is used in color making, either directly, as in the case of the azo colors, Meldola's Blue, and others, or after transformation into various sulfonic acids. It is largely used in dyeing and printing and for the development of p-nitraniline and other azo colors on the fibre.

It is also used in making pharmaceutical products, benzo-naphthol for instance, and for synthetic perfumes, Neroline, Yara-Yare and others.

Preparation of A-Naphthol

An analogous process to that adopted for b-naphthol is used, the alkalien fusion of a-naphthalene sulfonate of sodium.

About 2 parts of sulfuric acid of 66° Bé. are heated, not about 80° C., with one part of naphthalene to produce the a-sulfonate. The sulfonating kier already described is charged with 175 kilos of sulfuric acid, and, little by little, with constant stirring, 100 kilos of finely ground naphthalene are added, keeping the temperature above 50° C. When all the naphthalene is introduced, the temperature is raised to 80° C., and this point is not passed. The naphthalene is transformed into monosulfonic acid, and the operation is controlled by testing samples for solubility. When the greater part of the naphthalene is transformed, the contents of the kier are run into 2,500 litres of water, and the a-sulfonic acid sodium salt is separated either by partial neutralization with carbonate of sodium, or by precipitation with sea salt or sulfate of sodium, or by liming, which takes much longer. By alkaline fusion at 320° C., the sodium salt gives naphtholate of sodium. The a-naphthol is isolated exactly as described for b-naphthol, and distilled in a vacuum.

A-naphthol can also be prepared by hydrolysis of the salts of a-naphthylamine. For this purpose, 40 kilos of sulfate or hydrochloride of a-naphthylamine are heated at 200° C. for four hours in an autoclave with 200 litres of water. The following reaction occurs:—

$$C_{10}H_7NH_2HCl + H^2O = C_{10}H_7OH + NH_4Cl.$$

After cooling, the a-naphthol, which sinks to the bottom of the kier, is separated and purified by vacuum distillation. The ammonia is recovered by adding lime to the mother liquor and distilling it.

It will be noted that this process is the inverse of the previous one; it seems to be a more expensive method than that depending upon alkaline fusion, but gives a much purer product.

A-naphthol melts at 94° C., and distils at 279° C. It is sensitive to the action of the air, and turns brown eventually on exposure. It is used in the manufacture of azo colors, indophenol and naphthol Yellow S.

Naphthol Yellow S

In view of the importance of this color, which is not manufactured in France, it may be useful to give the formula for its preparation. Twenty-five parts of finely divided a-naphthol are dissolved in 100 parts of fuming sulfuric acid. This is done in a kier, provided with an energetic stirrer. The temperature is raised slowly to 120 C. to form the bisulfonic acid of a-naphthol. It is very important that the transformation should be complete, as otherwise the final product will contain dinitro-naphthol. The reaction is easily ascertained by taking successive samples; a little is diluted with water and heated with nitric acid; if the sulfonation is complete, there should be no yellow precipitate showing the presence of dinitro-naphthol.

If there is a precipitate a little more anyhydrous acid is added to the contents of the kier. When the absence of precipitate shows that the reaction is complete, the contents are allowed to cool and poured on 250 parts of ice, and then to the trisulfonic acid solution thus obtained 60 parts of nitric acid of 40° to 42° Bé. are added, and the temperature is raised to 50° C. and kept at this point until nitration is complete. The mass is then left to cool for twelve to twenty-four hours and filtered through sand. It is washed in salt water, then re-dissolved in water and neutralized with carbonate of sodium, and the dyestuff is precipitated in the form of sodium salt by the addition of salt. This is collected by filtration and dried with the usual precautions.

Naphthol Yellow S. is an important coloring matter for wool and silk. Dinitronaphthol, Martius Yellow, is obtained by preparing the naphthol-disulfonic acid, and acting upon this with nitric acid. This can also be produced by treating diazo-naphthalene with nitric acid. The diazo-naphthalene is itself prepared by the action of nitrite of sodium on a-naphthylamine. This coloring matter is used for tinting alimentary products, such as macaroni, although this use seems to be objectionable.

German Patents on Coal-Tar Colors

At the recent meeting of the National Association of Cotton Manufacturers in Springfield, Mass., a strongly worded resolution was adopted, calling for a confiscation, during the war, of German patents on dyestuffs which have not yet expired. The resolution was as follows:

"Resolved, That the National Association of Cotton Manufacturers earnestly urges the United States Government to take immediate steps similar to those taken by the Government of Great Britain to confiscate for the period of the war certain patents on dyestuffs held in this country by subjects of the German empire, thus providing for manufacture by reputable dye concerns, by a system of lease or other adequate method of control, which at the close of the war will assure fair compensation to the present owners of the patents."

There would seem to be no question but that the time has arrived when active steps should be taken to enable our expanding dyestuff industry to utilize the patents on several important groups of artificial dyestuffs, taken out by German inventors, since the beginning of the century. American dyers had become accustomed to these colors, especially to the various algol and indanthrene dyes, hydron, blue, immedial green and allied sulfur dyes, before the war and learned to value the exceptional fastness and ease of application. But a few years must elapse, in most cases, before the patent rights expire and the manufacture in the United States will be free to all. There would be, however, a most manifest advantage if our American color firms could make themselves so familiar now with the details of production that when the patents expire, after a return to normal conditions, the manufacture on a large scale, with a minimum cost of production, can be established without loss of time.

In this connection it is worthy of note that several leading American companies have secured lists of the German-owned patents which have been taken over by British firms since the beginning of the war. Among these are not a few dyestuff patents. There is little doubt that if the way is free, the production of the more important members of this group will promptly be established upon American soil.

Copper Compounds of Ortho-Oxy-Azo-Dyestuffs

The copper compounds of various ortho-oxy-azo colors, discovered recently by Wuth and Jagerspacher of Basel, have attracted attention on account of their vivid character. Dr. Gadient Engi, of Basel (Am. Pat. 1,245,694, of Nov. 6, 1917) shows that a certain class of these new colors is susceptible of further combination with chromium, and that the resultant products manifest a notably increased resistance to fulling and to potting. This class includes dyes with a free carboxyl group in the Diazo compound or a hydroxyl group and a carboxyl group in the component joined with it.

The results are obtained by dyeing the colors in question on chromium mordanted wool, or by using a bath containing chromatis or other soluble chromium salts, or by treating dyeings subsequently with the same chromium compounds.

The process is likewise available for dyeing and printing cotton, producing very fast tints.

The copper dyes in question are obtained chiefly from o-amino-salicylic acid, and its para derivatives (NO_2, Cl, SO_3H);

4-oxy-3-amino-1-benzoic acid;

1-amino-2-3-oxy-naphthoic acid;

2-amino-phenol-4-sulfonic acid;

2-amino-6-nitro-phenol-4-sulfonic acid;

3-amino-5-nitro-4-cresol; 2-amino-4-nitro-phenol;

1-amino-2-naphthol-4-sulfonic-acid.

These are diazotized and coupled with a great variety of components, phenols, amines, carboxylic acids or their derivatives, especially the sulfonic acids, to form dyestuffs.

The patent tabulates the results obtained from 70 of these mono-azo and disazo colors, after combination with copper, when dyed alone or after being subsequently chromated.

Ault & Wiborg Have Fire.

Ault & Wiborg, chemical manufacturers, of St. Bernard, Ohio, suffered considerable loss recently when fire destroyed one of the new frame buildings of their plant. The cause of the fire is undetermined.

By-Product Coke Plant of 330 Ovens.

A large by-product coke oven plant of 330 ovens will be constructed at Swedeland, Pa., by the Rainey-Wood Coke Co., and the Alan Wood, Iron & Steel Co., which have combined in order to carry out this project. It is expected to have the plant in operation within fourteen months. A complete by-product recovery plant for the purpose of furnishing ammonium sulphate and toluol to the U. S. Government will be a feature of the works.

An American Nomenclature for Synthetic Dyestuffs

The claim is advanced that the position of the American coal-tar color industry would be vastly strengthened if all dyestuffs made regularly in this country should be given distinctly American names, instead of the designations originally applied by the foreign inventors, or currently employed by foreign manufacturers.

John Campbell & Co., of 75 Hudson St., New York City, have issued a pamphlet on the subject, in which the argument is elaborated at some length. The presentation of the idea is quite forcible, as will be seen from the following extracts:

The development of the American Dyestuff Industry during the past few years, dating from the time of the beginning of the great world war, is a record of achievement that well deserves an enviable place in the annals of American business. The reason for our neglect of this industry during the many years prior to the war is an open question admitting of many different, well-founded opinions. Be the cause what it may it is a universally recognized fact that the entire world depended upon Germany for aniline colors and all nations were almost wholly and surely pitifully unprepared to meet the conditions brought about by the shutting off of this source of supply.

The American manufacturer has demonstrated to the world in a few short months that he is capable of building up a self-sustaining dyestuff industry. He has produced most of the simple colors and is now bringing out the more difficult colors; this the American manufacturer has done in the face of difficulties and obstacles that to a less determined people would have been deemed insurmountable.

Time, patience and a high degree of technical knowledge, as well as expensive equipment, are essential to the production of synthetic colors. The American manufacturer with rare faith in the ability of the American chemist has willingly invested his capital, cheerfully paid for the costly research work and necessary experiments and his faith in American brains has been rewarded by the joy of creating a great industry.

But is this great industry, representing even in its infancy an investment of many millions of dollars and created by countless days of effort, worry and anxiety while it was passing through the experimental stage, to be a permanent monument to the achievement of American business and chemical genius, or is it to be but a spasmodic industry, only bridging the time of the duration of the war until the German dyestuffs manufacturers cease making explosives and concentrate their efforts to the recapture of the business, the monopoly of which they so long enjoyed?

This question is a momentous problem with ramifications entering into every branch of American commercial life. We will devote a little space to the consideration of but one aspect of this problem and discuss briefly the influence of nomenclature, as the Germans have practiced it, upon the dyestuff industry.

It seems that a myth went up and down the earth a few years ago, that the Germans were a race of supermen. When a man or a cult representing a group of men claims superiority in any special line of thought or endeavor and constantly reiterates that claim, the world either dismisses them from its mind as bores or eventually believes them. The Germans as a nation admitted their superiority and the world chose to believe them.

The German nation has applied science to industry as has no other people. Even the influence of therapeutic suggestion, its recognized power to shape and dominate the opinion of others, has not been overlooked by them, but has been applied to business. The recognized power of this suggestive art to shape and dominate the thought and opinion of others has been systematically used in their various forms of propaganda. The world has been told from time to time that the production of coal-tar dyes was a peculiarly German institution; that they could not be made by other countries. This statement was accepted as a fact in the days preceding the war, but when the source of supply was shut off the American manufacturer soon got busy and punctured this German myth. We are producing most of the widely used colors which we had been told were impossible of production outside of German factories, and our manufacturers are now actually bringing out some of those more difficult colors which it has taken German chemists many years to produce.

But it is in the naming of their colors that the German manufacturers have displayed real sagacity and genuine business acumen and it is with this weapon of nomenclature that the American manufacturer must fight back. Each German firm as it produced various colors naturally christened them with names. At first each name really described a shade or color or indicated to which chemical family or group the color belonged. Later this custom was changed; an arbitrary, copyrighted word being given as a name which identified the color as a product of a certain German factory. Where several factories were producing the same shade or color, each factory gave its own special name. For instance, several German firms were making the same direct cotton color, a bright blue shade: one manufacturer called this shade "Diamine Blue," another gave it the name of "Benzo Blue," while other names used were "Chicago Blue," "Oxamine Blue," etc.

Now the American consumer will never willingly put himself in the position he occupied when the war shut off the supply of German colors. He realizes the necessity of having a dependable source of supply at home, and the only way this can be done is for the consumer of dyes to support the American dyestuffs manufacturer. No American mill man should use the German trade words for the name by which he has known colors in the past; to do so would be playing right into the hands of the German business propagandist. Therefore, let us be loyal to everything American, and among other things designate the American colors by their American names.

The project is certainly patriotic. Is it practicable?

We must consider the psychology of the consumers of colors. The great majority of these consumers are familiar with but a very brief range of colors, and are accustomed for years to foreign designations for these colors. Their knowledge of the chemical composition of dyestuffs is usually limited and dependence is placed chiefly on the very carefully drawn-up directions for using a dye as provided by the maker.

If such consumers are to be made familiar with an entirely new nomenclature for substances which they have handled for years, the operation should be made as simple as possible.

It would seem desirable in all such cases to associate, for a term of years at least, new American designations with those current hitherto for the foreign wares. When using a new, distinctively American name for a dye, on the label of a container or in a manual for directions for dyeing, it would be an easy matter to add in a parenthesis:

"Manufactured abroad under the names of ——, ——, etc."

Thus, a well-known azo dye has been manufactured in this country for a number of years and sold to the American trade under the name of Alizarol Yellow. If all packages of this color were labelled: ALIZAROL YELLOW, an American-made color (manufactured abroad under the name of Mordant Yellow GD, GS, R[B], Silicin Yellow D [K], Fast Chrome Yellow R [A], Alizarin Yellow G [S], Anthracine Yellow BN [C]), it would be comparatively easy for all users to associate the tinctorial value with the names to which they have been accustomed in the past. As a matter of fact, in the case cited above, some six additional titles could be added to make the list complete. The symbols in brackets indicate the manufacturing firms.

Such a system of labeling would enable consumers to act intelligently and easily in the case of rival colors. They would know at the outset that, chemically speaking, there is practically no difference between the dyes in question. The process of dyeing is the same in all cases. Minor variations in tint are due to blinding or intentional modifications in the operations of manufacture.

The main point is the exact amount of coloring matter available in a unit of weight, and the question of price will hinge upon this factor.

We should go a step farther than the contention of the firm quoted above. American-made dyes may properly receive distinctively American names, but all packages of the same should carry as clear and definite a statement regarding the strength as is now the current practice for synthetic indigo.

If this practice is made universal among American manufacturers of dyes, it will force their foreign competitors to adopt the same method. This will simplify enormously for consumers the problem of establishing actual competitive values between domestic and foreign products as well as between rival domestic producers.

This brings us, therefore, face to face with the problems of standardization. The position of this journal on this subject is well known.

18 Years of Chemical Progress

The Recovery of Potash

(Continued from page 290.)

lected ran at first from 5% to 6%. We have succeeded in bringing this up to an average of 9% or 10% and occasionally get as high as 14%. This seems to be about the limit for our style of treater but by using the principle of selective precipitation, there is no reason why it should not be brought up to 15% or 20%, depending on the richness of the raw mix.

Pure Potash Salts.

We have just begun to develop the possibilities of the production of pure potash salts but at present our market is almost entirely in the fertilizer industry. We have shipped to a large number of fertilizer manufacturers and our material has met with very general favor. It is particularly liked because of its fineness and physical condition. It also has some negatives and must be used with discretion. The lime content will cause reversion of the soluble phosphoric acid in mixed fertilizer if the material is added in excess. For this reason it has been found undesirable to use more than a certain proportion in fertilizer mixtures and it cannot be used satisfactorily to make very high potash goods. If the treater dust is very low in potash, it is unsatisfactory even for the manufacture of low potash goods. At the present time fertilizer manufacturers are not inclined to be critical of potash in any form but it is evident that when German potash is back on the market, a material containing less than 8% or 10% is not likely to be looked on with much favor.

Prospective Markets.

It is quite possible that a market for this material could be developed, selling direct to the farmer. It contains potash which is necessary to plant growth and lime which is necessary on most soils as a sweetener. The recombined potash contained in it is slowly soluble in soil acids and, therefore, gradually available to crops as needed. There are, however, practical difficulties in the way of developing this direct market. A vast amount of educational work would be necessary, the demand would be seasonable, and under present standard regulations for the sale of fertilizer, no credit could be obtained for the recombined or slowly soluble potash. It is probable that in the future this last objection may be overcome. A movement to this end would have the backing of Government experts but would necessarily be slow because of the number of people to be converted. It should be borne in mind that German potash has heretofore monopolized this market and all trade practices have been based on behavior of their material.

I have mentioned the fact that the recombined potash can be made soluble by long boiling, by digestion under pressure or by treatment with dilute acids. All of these methods are commercially feasible if the potash is sufficiently concentrated but it is obviously not profitable to treat a great volume of dust in order to recover a very small percentage of potash. For this reason concentration of the potash during collection should be a preliminary to any system of treatment for the recovery of the recombined potash.

Ideal Procedure.

Based on our experience and experiments, I would suggest the following as the ideal procedure in the collection of potash:

First, pass the gases at a relatively high velocity through a preliminary dry precipitator. The purpose of this would be to take out from 50% to 75% of the coarsest dust, which should then be returned to the kilns. With this dust would also be taken out a certain proportion of the potash, but this proportion would be small relative to the dust and would not be entirely lost, as it would pass again through the kilns.

The gases should not pass through a water film treater where the balance of the dust and practically all of the otash would be collected. The solution obtained here would be circulated through the water film treater until nearly saturated with potash salts and would then be evaporated by the waste heat of the gases for the recovery of these salts. The sludge containing the insoluble material would be treated in digesters at 100 lbs. pressure for one hour in order to liberate the recombined potash. It would then be filter pressed and the solution containing the potash would be combined with the original solution and evaporated. The filter press cake would be returned to the kilns. The cost of such a plant under present conditions would be in the neighborhood of $150,000 for a 3,000 bbl. plant.

Estimating Potash Recovery.

For the benefit of those who may wish to figure on their own conditions, I give the following method of calculating the probable recovery of potash:

Let A equal % potash in raw mix.
B " % potash in clinker.
C " % liberation $= \dfrac{600A - 380B}{600A}$
F " lbs. of potash recombined per bbl. clinker = .7 to 1.5 depending on fuel consumption and per cent. ash in coal.
P " % potash precipitated in treaters.

Assume 600 lbs. of raw mix actually used to make 1 bbl. of clinker, then: Lbs. of otash entering kilns per bbl. of clinker equals 600A.

Lbs. of potash volatilized in kilns per bbl. clinker equals 600AC.

Lbs. of water soluble potash entering treaters per bbl. clinker equals 600AC — F.

Lbs. of water soluble potash collected in treaters per bbl. clinker equals (600AC — F) x P.

Potash Prices May Hold Up.

At present prices for potash, almost any kind of recovery is profitable but there is no assurance as to how long present prices will continue, and the great question is whether recovery can be profitably continued after the war is over.

It is the trade custom to sell potash material on a basis of the units of pure potash contained; a unit being 1% of a net ton or 20 lbs. The present market price for agricultural potash is in the neighborhood of $5.00 per unit, whereas pre-war prices fluctuated between 60c. and 70c. per unit. In the opinion of those best acquainted with the industry, the price of potash will not drop to its former figure immediately on the close of the war, but it is thought likely that the price will remain relatively high for a number of years.

The cost of collecting potash at Security is now running about as follows:

Collection, including labor, power, repairs and laboratory	$0.14 per unit of potash
Packing and shipping	0.08 per unit of potash
Total operating cost exclusive of depreciation, royalty and salt addition	$0.22 per unit of potash

The cost of the salt addition is about $0.25 per unit of potash, but this is not a necessary element of cost and can be omitted whenever price conditions become such as to give an unsatisfactory margin of profit.

These figures cannot, however, be applied to other plants because nearly all the elements of cost are constant per day irrespective of the amount of potash recovered. The following figures taken in connection with the calculated recovery will give a basis for estimating cost in any particular case:

Labor required for operation—1 foreman (who can also supervise packing and loading) and 1 or 2 operators per shift; about $12.00 per day.

Laboratory—1 additional chemist, say $4.00 per day.

Power—1,300 kw. hours per day for 3,000 bbl. plant, based on dry collection plant—about $12.00 per day. A wet treater would require additional power for pumps to handle solution.

Cost of operating digesters and evaporators or of packing and loading dry dust not included above.

Cost of adding salt to raw mix will run about 2.2c. per bbl. of clinker at present prices for salt. It would be reduced to about 1.6c. per bbl. in normal times.

Cost Calculations.

The following is an example of the methods of calculating probable costs and profits:

Assume a 3,000 bbl. plant; .75% potash in raw mix—70% liberation when using 1% salt; 10% ash in the coal and 90 lbs. of coal used per bbl. of clinker; 0.9 lb. potash recombined per bbl. of clinker; 90% collection in treater.

Using selective precipitation and water film type of treater, also treatment of slurry for liberation of recombined potash and recovery of pure potash salts by crystallization.

Lbs. of total potash collected in treater per bbl. of clinker equals (600 x .0075 x .7 x .9) or 2.835 lbs.

There will be a loss of about one-half of the potash collected in the preliminary treater and returned to the kilns. This will amount to about 15% of the total collected. There will also be some loss in the digesting and crystallizing process which, to be conservative, we will assume to be 10% of the potash so treated. On the other hand, there is no loss through recombination since the digesting process renders this recombined potash water soluble. Hence net water soluble potash recovered per bbl. of clinker = 2.835 x .85 x .90 = 2.078 lbs.

This potash would be in the form of relatively pure crystallized salts and there would be no question as to its salability.

Operating costs and profits would work out about as follows:

Operating cost—

Labor	$ 27.00 per day	.0090 per bbl. clinker
Power	25.00 per day	.0083 per bbl. clinker
Repairs	8.00 per day	.0027 per bbl. clinker
Laboratory	120.00 per mo.	.0014 per bbl. clinker
Salt addition		.0220 per bbl. clinker

	Present Price.	Assumed After War Price.
Sales price per unit of potash	4.50	$1.00
Value of potash collected by bbl. of clinker	.4675	.1039
Operating cost per bbl. clinker	.0434	.0434
Operating profit per bbl. clinker	$0.4241	$0.0605
Operating profit per year based on full operation of cement plant	$458,038	$65.340

This result does not allow for depreciation, royalty or loss due to part time operation of cement plant.

Effects on Operation of Plant.

No doubt the first thought of every cement manufacturer will be as to the effect of potash recovery on the operation of his cement plant. There is a possi-

HELP WANTED

PRACTICAL EXPERT wanted in manufacture of food products; one knows how get results from raw materials; give experience, reference, etc. C., c/o Chemical Engineer.

MECHANICAL AND CHEMICAL ENGINEER—A manufacturer wants a man with above qualifications to help develop his present method of production; state detail experience, age, and salary expected. Write Engineer, Room 611, World Building, New York City.

WANTED, ANALYTICAL CHEMIST FOR FERTILIZER FACTORY. A fine opportunity for an energetic and ambitious young chemist understanding machinery and with knowledge of heat engineering and practical chemistry. Write "V. C.," c/o Chemical Engineer.

CHEMIST, with Belgian diploma and experience in sugar derivatives (sugar, alcohol, and perfumes), and Professor of Spanish and French, wants position; without experience in other branches of chemistry; accept position as assistant. Write to G. A., 338 West 45th St., New York, N. Y.

bility of its affecting output, fuel consumption and quality. As to these points, our experience at Security should be of interest.

The effect on output has been negligible. For the first few weeks of operation at the potash plant we had some trouble with our drafts and output was decreased. Following this came a period when it surpassed all previous records. This, however, we know to have been due to other conditions and to have no direct bearing on the potash plant.

Fuel Consumption Reduced.

In our case, the addition of the potash plant has reduced our fuel consumption. For 5 months in 1916 without the potash plant our fuel consumption averaged 96.4 lbs. per bbl. For 5 months in 1917 with the potash plant, it averaged 87.0 lbs. per bbl. This has been brought about through more careful attention to the temperatures at the back end of the kiln. Whereas these temperatures at one time fluctuated wildly, they are now almost perfectly uniform and average much lower.

There is no evidence that the addition of the potash recovery plant has had any effect whatever on the quality of our cement except that there has been a tendency toward harder burning since we have found that harder burning gives a better recovery of potash. Some question has been raised as to the possible effect of the salt addition on quality, as it is known that the presence of an excessive amount of alkalies in the clinker may under certain conditions cause setting troubles. Strange as it may seem, however, we have found that the addition of 1% salt to the raw mix results in a lower percentage of total alkalies in the clinker than when no salt is added. Obviously if the salt does not go into the clinker but is practically all volatilized and passed out with the gases, it can have no possible effect on quality. As a matter of fact, we have experienced no quality troubles which could in any way be traced to the use of salt and the fact that a Western plant, as before mentioned, is reported to use regularly a raw mix containing as much as 5% salt is also evidence that this material is not injurious.

No Change in Manufacturing Methods.

I would emphasize here the fact that the collection of potash does not involve any change in present methods of manufacturing cement. It is simply the recovery of a by-product that is now going to waste and is in line with present tendencies towards the conservation of raw materials and increased efficiency in manufacturing.

I have spoken of the possibilities through the use of feldspar and other high potash materials. There are only a few existing cement plants which can do this to advantage as not only must a regular supply of good feldspar be close at hand but the limestone used with it must be high in lime and there must be, either in the limestone or elsewhere, a supply of alumina or iron oxide to offset the high silica of the feldspar. Under such favorable conditions, it is possible to get a mixture containing as high as 2.5% of potash and a recovery of 7.5 lbs. of potash per bbl., equivalent at present prices to $1.875 per bbl. In other words, under very favorable conditions the potash may easily become the principal product of the plant in value and the cement be relegated to the position of a by-product.

Recovery Pays for Itself in Year.

In conclusion I would say that the Security Cement & Lime Company has been very well repaid for its venture into this comparatively new field. Our gain by acting promptly and thus reaping the full benefit of high prices has far more than offset the loss through our failure to get the benefit of others' experience and the very best type of installation. We have had many anxious moments and much hard work in bringing the enterprise to a successful conclusion, but all is well that ends well. Now with the cost of our plant more than returned to us from the profits of the first year's operation and with our profits from the sale of potash in excess of those from the sale of cement, we feel that our efforts have been abundantly justified.

Spun Glass in Endless Lengths.

In Venice, for many years, the art of glass spinning was fostered, until this city became known for the great beauty of the ornamental objects which it put on the market.

There have always been shortcomings in the work, due to the fact that glass thread could be spun only to the length of the circumference of the wheel on which it was worked, and this was never more than eighteen feet.

This difficulty has been overcome by an American manufacturer, who can make spun glass thread into endless lengths, and put it on spools as is done with ordinary threads. This enables a multitude of objects to be made, that could not be made before. The threads of glass can be made in all colors, giving a world of brilliancy.

Because of being fireproof, spun glass curtains, for fireplaces and as draperies and hangings in theatres, hotels and public places, are unequalled. Many wonderful and beautifully hued millinery trimmings are made from the braided glass. The glass thread can be interwoven with silks, cottons, wire, etc., giving an endless variety of combinations. Dancing dresses for stage people have remarkable novelty.

Technical Uses.

Probably the largest field of use will be in the technical and engineering fields, where it already has a foothold. Because of the difficulty of working constantly under the extraordinarily strong light of the moving picture studios, the producers have taken to glass-woven cloths as light diffusers, with splendid results. As absolute non-conductors, glass plates for storage batteries will give longer life than present day plates. For insulation of electric wires, instruments, etc., the glass thread can be used. As an example of its non-conductivity, power house workers have had the soles of their shoes bottomed with spun glass plates, to avoid shock. For the filtration of acids, glass plates are excellent.

There are a world of uses for this new product, and L. Reusche, of the Reusche Company, who manufacture the product, states that each field will be developed thoroughly with the thought of giving general distribution of its many advantages.

A Special Filter Paper for Every Filtering Need.

Some factories still depend upon a rule-of-thumb or guess-work system of choosing filter papers for the various filtering processes they use in their manufacture, and fail to get maximum efficiency from their work.

While the average factory ordinarily uses the filter paper that approaches the best possible, there are just the slightest shades of difference between the many needs, that only the expert filter paper man can decide on the right grade to use.

H. Reeve Angel & Co., of 7 Spruce Street, New York City, are experts in the advisement of factories on the proper papers to use because of their many years of service in the field.

The following brief classification of filtering needs and papers to meet them has been made by them and gives only a slight idea of the possible differences among papers.

Qualitative Papers.

1. For general work.
2. For fine precipitates; very rapid.
3. Heavy; for the finest precipitates.
4. For gelatinous and large particle precipitates; extremely rapid.

Single Acid Wash.

1. For fine precipitates; very rapid.
2. For gelatinous and large particle (not free) precipitates; the most rapid filter paper made.

Double Acid Wash.

1. For general quantitative work.
2. Very rapid; not for use with fine precipitates.
3. For extremely fine precipitates; for use with or without vacuum.
4. Lower ash than above mentioned for most exacting analyses.

This only gives a comparative idea of the classifications made by the H. Reeve Angel company. Representatives of this firm are always ready to give advice to any manufacturing and practicing chemist as to the best papers to use for the particular work he is specializing in.

New London Chemical Co.

The New London Chemical Co. has been incorporated with a capital of $50,000 at New London, Conn., to manufacture chemicals and allied products. The incorporators are: Bert W. Flanders, Ira M. Comstock and H. E. Harris, New London.

Will Manufacture Coke and Chemicals.

With a capital of $100,000 the Chicago Coke & Chemical Co. has been incorporated at Portland, Me., to operate a plant for the manufacture of chemicals, coke, iron, etc. Incorporators are: P. B. Drew, C. G. Trott and D. F. Drew, Portland.

New Dyestuff Manufacturers.

To engage in the manufacture of dyestuffs, the Colonial Aniline Works has been incorporated with a capital of $10,000 at Monticello, N. Y., by P. S. Glickstein, W. and C. Lowenthal, Brooklyn, N. Y.

Earle Chemical Co.

Chemicals and allied specialties will be manufactured by the recently incorporated Earle Chemical Co. of Wheeling, W. Va. The capital is $50,000 and the incorporators are: R. I. Runner, E. H. Draker, Eugene Hill, Raymond Sypher and C. Rader, of Wheeling.

News Notes of Chemical and Allied Industries

Permutit Co.'s New Home.

The Permutit Co., of New York City, manufacturers of water softening devices, have moved from 30 East 42nd street into their new offices at 440 Fourth avenue.

New Building for General Chemical Co.

At Marcus Hook, Pa., the General Chemical Co. of New York is about to begin the construction of a new one-story service building at a cost of $100,000.

Bond Chemical Co.

Chemicals and allied products will be manufactured by the newly incorporated Bond Chemical Co. at Camden, N. J. The capital is $125,000 and the incorporators are John J. Finney, Joseph Mallon and F. M. Wick, Camden.

Western Chemical Products Co.

The Western Chemical Products Co. has been incorporated with a capital of $25,000 at Vernon, Cal., to manufacture chemicals, by G. W. Marchand, Long Beach, W. T. Moore, Long Beach, and T. C. Yeager, Canton, O.

Prof. Loy Forsakes Chair for Business.

Prof. S. K. Loy, professor of chemistry at the University of Wyoming, has tendered his resignation to enter the commercial world as chief chemist of the Midwest Refining Co., Casper, Wyo.

To Remodel Laboratory.

At an estimated cost of $20,000 the Bureau of Yards and Docks, Navy Department, Washington, D. C., will remodel its chemical laboratory at Indian Head, Md.

Basic Phosphate Fertilizers.

At Birmingham, Ala., the National Basic Fertilizer Co., has been incorporated with a capital of $137,000 to manufacture basic phosphate fertilizers. The incorporators are C. E. Elgin, Searls, Ala., J. W. Lowman, Albany, N. Y., and W. S. Oglesby, Searls.

Butterworth-Judson to Rebuild Plant.

Plans are being rapidly completed by the Butterworth-Judson Corp. for the reconstruction of its plant in Avenue R, Newark, N. J., which was recently destroyed by fire with an estimated loss of $200,000.

Grasselli's New Acid Plant.

Work has been begun on the new local acid manufacturing plant of the Grasselli Powder Co. at Cleveland, Ohio. The new plant represents an investment of about $1,000,000.

To Manufacture Potash Salts.

J. B. Speed & Co., Louisville, Ky., is planning the expenditure of $100,000 for the erection of a potash manufacturing plant at Lockland, that state.

To Manufacture Cement Products.

Cement products will be manufactured by the recently incorporated Waterproof Cement JProducts Co., which has been organized at Norfolk, Va., with a capital of $100,000.

Scarcity of Dyestuffs in Java.

A recent report from Java indicates that there is a great scarcity of all kinds of dyestuffs there. Manufacturers interested can obtain information as to trading facilities from the Bureau of Foreign and Domestic Commerce, Washington, D. C.

Will Help Furnish Sinews of War.

H. Koppers Co., Pittsburgh, Pa., will have charge of the erection of a $110,000 plant for the production of toluol from gas which the U. S. War Dept. will locate near the works of the New Haven Gas Co., New Haven, Conn.

A Correction.

In our June issue we chronicled the good fortune of the Duriron Castings Co., New York City, in securing the services of Mr. Arthur Hough in the capacity of consultant. The spelling of Mr. Hough's name, however, should have been as it appears herewith, and not "Howe," as given in the news item referred to.

Fifty New Coke Ovens Building.

A battery of twenty-five Wilputte coke-ovens is to be added to the original twenty-five with which the Algoma Steel Corporation had planned to enlarge its plant at Sault Ste. Marie, Ontario. This makes a total of fifty new ovens now in process of construction at the plant, and it is expected that these will be ready for operation before the first of the year.

Redwood Tanks for Storing Fuel Oil.

Of extreme interest to users of tanks comes the news that at the behest of a concern whose name is withheld, the Acme Tank Co., New York City, has recently completed the installation of a battery of twelve 6,000 gallon redwood tanks for the storing of fuel oil. Although steel tanks are customarily employed for this purpose, the difficulty of obtaining the metal led the purchaser to cast about for a suitable substitute, with the result that, after careful consideration, it was decided to employ tanks built of pure California redwood, which the Acme Tank Co. specializes in.

NEW PUBLICATIONS

"Mining and Concentration of Carnotite Ores."

"Mining and Concentration of Carnotite Ores" is the title of Bulletin 103, recently issued by the Bureau of Mines, Department of the Interior, the authors being Karl L. Kithil and John A. Davis.

In a review of the work on radium by the Bureau of Mines, Van H. Manning, director, says:—"In 1912 the Bureau of Mines had its attention called to the value of the carnotite ore of Colorado and Utah as a source of radium and to the need of investigations being made to prevent waste of low-grade carnotite, to enable the miner to receive a better price for his product, and to insure the profitable recovery of the highest possible proportion of the radium in the ore. The need of comprehensive research was increased by the carnotite deposits being situated on public lands and constituting the largest known supplies of radium ore in the world. Fortunately the Bureau was able to interest Dr. James Douglas, of New York City, and Dr. Howard A. Kelly, of Baltimore, Md., who wished to procure a supply of radium for use in the treatment of cancer in hospitals with which they were connected. The suggestion was made that they form a radium institute. Accordingly, the National Radium Institute was incorporated for the purpose of studying the best methods of producing uranium, vanadium and radium, and the mining and concentration of ores from which these products may be obtained for use in radium therapy.

"Subsequently, at the suggestion of the institute, a co-operative agreement was made under which the Bureau of Mines undertook to provide the services of skilled chemists and mineral technologists for the supervision of the mining and concentrating of the carnotite, and the National Radium Institute agreed to furnish the necessary funds for mining and concentrating a sufficient supply of ore and for recovering from it the radium, uranium and vanadium. Under this agreement a radium-recovery plant was built in Denver, Colo. The plant began commercial operation in June, 1914, and when it stopped work in January, 1917, about 8½ grams of radium had been extracted. The cost of recovery under the methods devised by the Bureau of Mines was only about one-third the current price for radium. In addition, methods of saving the uranium and vanadium in the ores and of obtaining the metals in a pure state were perfected.

"The agreement between the National Radium Institute and the Bureau of Mines expired in 1916. As a result of the work under this agreement, the Bureau of Mines has been able not only to demonstrate that radium can be produced at a cost much less than the selling price, but it also has been able to show how losses in mining and concentrating carnotite can be prevented and our resources of this wonderful element conserved. Finally, for an expenditure of less than $38,000, the bureau has received as its share of the results of the co-operative agreement more than $180,000 worth of radium.

"The work of the Denver plant was discussed in Bureau of Mines Bulletin 104, 'Extraction and Recovery of Radium, Uranium and Vanadium from Carnotite.' In the present bulletin, K. L. Kithil, mineral technologist, and J. A. Davis, assistant mining engineer, describe the methods used in mining and concentrating the carnotite treated at Denver. As the workable carnotite deposits of Colorado and Utah, though lying near the surface, are relatively small, very greatly in richness, and are extremely irregular in distribution, methods such as are ordinarily used for prospecting and mining shallow deposits have to be modified. Also, it is necessary to examine the ore carefully, sort it closely, and frequently test its radium content with the electroscope. Finally, the carnotite deposits are mostly in an arid region, where water for any purpose is scarce, so that dry rather than wet methods of concentration must be used at most places. Hence the authors have given detailed information in regard to many operations that might receive little notice in an account of the mining of most metals, but

the presentation of these facts in regard to carnotite is necessary because of their bearing on profitable mining and concentration, the utilization of low-grade ore, and the prevention of waste."

The "American Fertilizer Handbook" for 1918 Now Ready

The happenings of the past year have been of unusual importance and value to everyone interested in the fertilizer industry and its allied trades. By virtue of their character, fertilizers play an important part in food conservation, and for that reason the Government has been operating directly with the members of the trade, through the Committee on Fertilizers of the Chemical Alliance.

The secretary of this committee is Mr. John D. Toll, who is also editor of the "American Fertilizer Handbook," just issued from the press of Ware Brothers Company, Philadelphia, 1918. Because of the fact that Mr. Toll spends fully one-half of his time in Washington for the express purpose of keeping in close and constant touch with the Government on this subject and to assist the committee in its work, he has, therefore, in compiling the 1918 edition of the American Fertilizer Handbook, been able to include all this important information, thereby rendering this work more valuable and complete than ever.

In addition to the usual directories, so useful to the trade, it contains condensed information on all important fertilizer facts which have transpired during the year, all under one cover and handy for ready reference. It constitutes a work which should be in the hands of everyone interested in the advancement of the industry in this country.

First Two Government Picric Acid Plants.

Contracts have been awarded by the Ordnance Dept. U. S. A. for the erection of two large plants for the manufacture of picric acid. The plants will be located at Little Rock, Ark., and at Brunswick, Ga., and will cost $4,000,000 and $7,000,000 respectively. The Everly M. Davis Chemical Corp. will erect the Little Rock plant, while the Butterworth-Judson Corp., of New York City, will erect the works at Brunswick. These will be the first government controlled picric plants to be established in this country.

Du Pont Enlarging Haskell Plant.

Construction work has been begun on an addition to the E. I. DuPont de Nemours Co.'s plant at Haskell, N. J. The addition is one-story, 20x40 feet.

O'Brien Synthetic Dye Co.

The O'Brien Synthetic Dye Co. has been incorporated with a capital of $50,000 at South Bend, Ind., to manufacture dyestuffs, chemicals, etc. The incorporators are Jerome J. Crowley, George L. O'Brien, Will G. Crabill, S. J. Crumpacker and Ray Heylman, South Bend, Ind.

Our New Factory for the Manufacture of Pure Fused Silica, known as

SiDiO

has just been opened in New York City. A part of the output has already been assigned to the Government, but production is on such a scale as will enable us to meet your needs promptly.

SIDIO Ware is coming into wide use, both because of its low cost compared to platinum and other wares which it replaces, and also because of its technical superiority.

SIDIO withstands rapid temperature changes, it may be exposed to a continuous temperature of 1200° C. SIDIO has a coefficient of expansion one-seventeenth that of glass or platinum.

SIDIO is especially adapted for Combustion and Pyrometer Tubes, Sulphuric and Nitric Acid Condensing and Cooling Apparatus, high temperature gas analyses.

During the National Exposition of Chemical Industries to be held at Grand Central Palace, New York, week of September 13th, 1918, we shall occupy booth 45 on the main floor and display a representative line of our articles.

Tickets for Chemical Exposition

Readers of the Chemical Engineer who can make use of tickets to the Fourth National Exposition of Chemical Industries to be held at the Grand Central Palace, New York City, during the week of September 23, can obtain them by writing to this office. The Chemical Engineer will be glad to accord a hearty welcome, together with whatever services or information it may be within our power to furnish, at Booth 465, which will be located at the extreme rear of the third floor, close to the entrance of the Motion Picture and Conference Hall. (Take elevator.) Our readers are cordially invited to make this booth their headquarters. Let us know your requirements as soon as possible, and your tickets will be forwarded at once, with our compliments.

A Luxury for the Industrial Chemist

The old saw which calls attention to the sudden deep and abiding public interest in the dearth of water when once the well chances to run dry, never received a more forcible demonstration throughout the entire course of its long and useful career than it did in this country in the Year of Dis-Grace, 1914, when the Teutonic wells from which we had been merrily drawing our principal supply of synthetic drugs, dyes and other chemicals—with never a thought of the morrow!—all "ran dry" with an abruptness and a unanimity which fairly took our breaths away and left us floundering about in a mad attempt to stave off one of the most serious industrial droughts which ever threatened these United States.

But once the first shock was over and we began to take account of our needs, the chemists of this country set quietly and methodically to work to supply them. At first there were the really vital fundamentals to be seen to; potash and nitrates, and, almost as pressing, important intermediates for the production of synthetic drugs and medicinals, dyestuffs and explosives, were of necessity our chief concern for the time being. We also were in urgent need of many forms of laboratory apparatus to aid us which had likewise constituted one of the principal streams from these self-same German and Austrian wells.

From that time forward our record has been one of steady progress as, step by step, we have systematically conquered one difficulty after another until, at length, we have at least attained a point where our major necessities are pretty well provided for. We are not, of course, as yet in that ideal state where we can sit back in the calm realization that we are sufficient unto ourselves so far as depending upon outside sources is concerned, but at least we know where much of these products is coming from in future, and we know that the continued application of research through the next few years will bring us continually nearer to this goal.

We *are* in a position, then, where we can draw breath and turn part of our attention to some of those less vital and more highly complex products which constitute the luxuries, so to speak, of our industrial chemical life. This fact is amply proved by the news of a project now being undertaken by a firm whose practically unlimited facilities, capital and staff of technical men give every assurance of its being carried out successfully.

Of more than usual interest to the chemical fraternity in general and to users of some of the rarer and more difficultly obtainable organic compounds in particular, comes the announcement from Dr. C. E. Kenneth Mees, of the Eastman Kodak Company, that this concern is about to establish a separate section of its laboratory, to be known as the "Department of Synthetic Chemistry," for the sole purpose of filling in the gaps which at present exist in our supply of these reagents for research and industrial purposes.

In a communication to this journal, Dr. Mees sets forth the details of the project as follows:

"In order to provide for the supply of organic reagents for research and industrial purposes the Eastman Kodak Company has determined to commence their preparation in its research laboratory.

"This decision was arrived at as a result of the articles published by Dr. Roger Adams and of a recent letter by Professor Gortner in "Science" (June 14, 1918, p. 590), which drew our attention to the need for an adequate supply of these materials produced by a firm of standing.

"In order to carry on the work a separate section of the laboratory has been established under the title of the "Department of Synthetic Chemistry," which will be under the immediate direction of Dr. H. T. Clarke, well known for his publications on organic chemistry.

"In order to make available to research laboratories in this country the organic chemicals which they require, it is proposed that chemicals for research work shall be supplied at the lowest possible price. At first, no doubt, this price will necessarily be higher than that charged by the German firms before the war, but it is hoped that eventually the profit made on chemicals supplied for commercial purposes may enable the rarer materials made in small quantities for research work to be sold at a price which will be within the reach of all who require them.

"At first, of course, the laboratory will be able to supply only a limited number of substances, and these in small amounts, but the department will be expanded to meet the demand and with the assistance of other laboratories interested in organic chemistry, and of the firms who are producing dyes and intermediates, it is hoped that after a time an adequate supply of synthetic organic reagents can be made available.

"It is possible that laboratories may have in stock unusual reagents which they are unlikely to require. If any laboratories possessing such reagents will write to us we shall be glad to make an offer for the materials, thus making them available on the market.

"Our thanks are due to many of the chief chemists of the country who have encouraged us to commence this work and especially to Professor Roger Adams for the way in which he has received our proposals and has assisted us by placing at our disposal the information as to this work which he has accumulated.

"Communications regarding reagents should be addressed to the Research Laboratory, Eastman Kodak Company, Rochester, N. Y."

The project is not only thoroughly patriotic, but in addition will fill a long-felt want and should prove of inestimable value to the country at large as time goes on and the new department's repertoire of available reagents grows in volume.

The determination of the firm to essay the dual role of producer and clearing house serves to indicate more strongly an unselfish desire to further the aims of our industrial chemists and research men and in this way to hasten our approaching independence.

The originators of the undertaking are deserving of the highest commendation, and we feel sure that readers of this journal will join us in wishing them every success in its development.

One Way to Help

Through the Editorial Conference of the New York Business Publishers' Association, A. Mitchell Palmer, Alien Property Custodian of New York, has recently issued the following statement regarding the law relating to enemy-owned property in this country which, it is hoped, will indicate clearly to readers of the Chemical Engineer just how they can aid in rounding up additional properties at present unlawfully held. Mr. Palmer's statement follows:

There are two ways of making war against an enemy. One by force of arms; the other by force of economic pressure.

When a nation wages economic war it brings to bear upon the enemy every force it can muster to stop his supply of food, money and munitions and thereby make him weak and impoverished.

The day the United States entered the war there was in this country millions upon millions of dollars belonging to Germans. It was invested in mines, factories, banks, steamships, farms, plantations, etc. Its total amount might run into billions. We had no way of estimating then. But we did know that it was German gold that was colonizing industries here in America and that it was good American money that was being shipped back to Berlin in the form of earnings to enrich the German nation, to fill the war chests, to help complete its great plan for a world control of commerce and industry.

When war was declared the Army and Navy started to mobilize men and guns, the Shipping Board to build the fleet; the War Trade Board to cut all commercial relations with the enemy, and the Alien Property Custodian to gather into the Treasury of the United States every penny of German-owned money that could be found. That is why the office of the Alien Property Custodian was created.

The duties of the Alien Property Custodian are exactly what the name implies, only in addition to the work of taking over and administering holdings of enemies, he has been given power by Congress to sell outright these properties belonging to the great industrial and corporation classes of Germany planted here in America.

In order to help, it is important to know just *who* is an "enemy" and *what* is "enemy" property.

Enemy property includes any and every kind of property, money, chattels, securities, lands, indebtedness, accounts receivable, etc., which belongs to an enemy. Even if the property is held in the name of another—by a dummy or in trust—if the real beneficial interest belongs to an enemy, it is enemy property.

An enemy under the Act is:

1. Any person regardless of citizenship or place of birth who is within the boundaries of Germany, Austria-Hungary, or their allies, or within the territory actually occupied by their military or naval forces. A peaceful and law-abiding German or Austrian citizen residing in the United States is not an enemy; but an American citizen living in enemy territory is an enemy.

2. A person residing outside of the United States and doing business within the territory of enemy countries or their allies.

3. A corporation, if incorporated within the territory of enemies or their allies, or incorporated in any neutral country and doing business within the territory of enemies or their allies.

4. An official or agent of an enemy Government or any subdivision thereof.

5. All natives, citizens, or subjects of Germany or Austria-Hungary interned by the War Department.

6. All citizens or subjects of Germany or Austria-Hungary resident outside of the United States who are (a) wives of officers, officials or agents of Germany or Austria-Hungary, wherever resident; (b) wives of persons within the territory (including that occupied by military and naval forces) of Germany or Austria-Hungary; or (c) wives of persons resident outside the United States and doing business within enemy territory.

7. Citizens or subjects of Germany or Austria-Hungary who are prisoners of war or who have been or shall be interned by any nation associated with the United States in the war.

8. Citizens or subjects of Germany or Austria-Hungary who since April 6, 1917, have disseminated or shall hereafter disseminate propaganda to aid any enemy nation or to injure the cause of the United States, or who have assisted, or who shall assist in plotting against the United States or any nation associated with the United States in the war.

9. Citizens or subjects of Germany or Austria-Hungary who are included or who shall be included in the "Enemy Trading List" published by the War Trade Board.

10. Citizens or subjects of Germany or Austria-Hungary who, at any time since August 4, 1914, have been resident within enemy territory.

Note—Numbers 2, 6, 8, 9 and 10 apply only to persons resident outside of the United States.

Three quarters of a billion dollars worth of property have been reported to the Alien Property Custodian at Washington today, but from our investigation throughout the country we know that there is much more not yet located. Here is where the citizens can render valuable assistance.

You can help the nation by mailing the Bureau of Investigation, Alien Property Custodian, Washington, D. C., reports or information on enemy owned property in your vicinity. You are shareholders in this great combination trust company, department store, and auction sale, now run by the government, and the larger you swell its holdings the more you will back up the Army and Navy now battling against the Hun.

Thrift Stamp Purchases

There Should Be No Let-Up During the Remaining Months.

With the advent of the hot weather a falling off in the sales of Thrift and War Stamps may be expected unless the efforts of the patriotic workers are not suffered to diminish. There need be no falling off in the sales, however, if we all keep our heads and continue to view the situation sanely and clearly. Let each one of us ask himself or herself whether the need for co-operation is as great among the Allies as it was and then, when we have answered our own question in the affirmative (and who could answer it otherwise?) let us make up our minds at once that while the need exists the money shall be supplied. There were a million reasons advanced during the last Liberty Loan campaign why every one should subscribe and induce others to do likewise, and there was not a reason advanced at that time that does not apply with just as much force to the War Savings Stamps now.

Some one may say, "But I've bought stamps until I'm almost broke," and they may really feel that they have a valid reason for not buying more, but people who talk like that have failed to grasp the significance of the situation. Such people do not stop to consider their sacrifices as compared to the sacrifices that are being made daily, hourly by the young men of America who are on the firing line in Europe.

There really should be no need to plead with any one to buy stamps and thus have a part, though a small one, in this the greatest movement in the history of man. Every individual should consider this not alone a duty, but a great privilege. Now, viewing the matter from another angle, divesting the question of all sentiment, patriotism and obligation, let us consider it as a matter of dollars and cents.

And let us remember right at the start that we are not giving, we are receiving. We lend on the best security in the world and in five years the loan is returned with interest. But that is not all. Let us also remember that after peace has been restored and conditions return to normal the purchasing value of the dollar will be greater by far than it is now, so that every dollar saved now will doubtless do the work of two or more in a few years.

There is nothing new in the foregoing, but for the sake of emphasizing the importance of the War Savings Stamp campaign let us continue to keep this important matter before the people.

—*Charles Ross Keen, in New York "Evening Sun."*

Equitable Sulphur Distribution

Resolutions were passed at a recent meeting of the Chemical Alliance pledging the organization's co-operation with the Chemical Division of the War Industries Board in the allocation and distribution of sulphur-bearing materials during the war. There is no shortage of sulphur for the manufacture of sulphuric acid and other chemicals vitally necessary in the manufacture of munitions, it was said, but in order that distribution might be perfected and all munition plants receive their full share of raw materials the Chemical Alliance would share the burden of distribution with the board.

A committee was formed to confer with officials of the Chemical Division in the matter of distribution. It was said that a tremendous increase in the output of sulphuric acid was in prospect because of the demands made by munition plants. The committees will see to it that the acid is not used in non-essential manufactures to the disadvantage of the ammunition output. There are more than 250 acid plants in the United States receiving their supplies from the Gulf Coast region, and a regulation of the supply was considered necessary. Horace Bowker of the American Agricultural Chemical Company, 2 Rector street, presided at the meeting. The Government was represented by Charles A. MacDowell, Chief of the Chemical Division of the War Industries Board.

Government Seeks to Increase Coke Output

Announcement has been made recently in the press that new processes for the production of coke are now being sought by the government, Secretary Redfield having authorized the Bureau of Standards to make experiments with two methods of coking high-volatile coal, the Koppers method used by a plant in St. Paul, Minn., and the Roberts process, in operation at Canal Dover, O., either of which, if proved commercially practicable, would increase greatly the output of by-product coke by permitting the use of coal hitherto considered unsuited for coking. Transportation conditions also would benefit, it is said, through the utilization of coal from almost any field, instead of from the restricted area where coking coal now is produced.

Laboratory tests of the Roberts process virtually are complete, and the Bureau of Standards expects to take over operation of the Canal Dover ovens soon with the consent of the owners, for further experimentation.

To Standardize Petroleum Products

The appointment of a committee, which will act under the U. S. Fuel Administration, to standardize petroleum products, has been authorized by President Wilson. The purpose of the committee will be to fix standards to be used in the purchase of petroleum products by the United States and allied Governments in this country. The standard to be determined will replace the English standard now generally used in the United States and it is expected will be extended gradually to commercial use.

The committee, as authorized by the order, will consist of a chairman appointed by the Fuel Administration and representatives of the War and Navy departments, Shipping Board, Railroad Administration, Bureau of Mines, and Bureau of Standards.

Freeburn Joins Wallace & Tiernan Staff

H. M. Freeburn has resigned as Assistant Engineer of the Pennsylvania State Department of Health to become associated with the Engineering Staff of Wallace & Tiernan Company, Inc., New York City, manufacturers of chlorine control apparatus and sanitary engineering specialties.

Following his graduation from the Sanitary Engineering course of the Pennsylvania State College, Mr. Freeburn was an instructor at the institution and was in charge of experimental sewage work. Subsequent to this, he was associated with the Engineering Branch of the Pennsylvania State Health Department.

Geisenheimer Dissolves

Announcement has been made of the dissolution of the firm of Geisenheimer & Co., owing to the retirement of Theodore Geisenheimer from business. The property and assets formerly belonging to the firm have been acquired by Aniline Dyes & Chemicals, Inc., of which Alfred F. Lichenstein is president and treasurer. The first vice-president of the concern is W. H. Van Winckel, formerly sales manager for the Dow Chemical Co., and the second vice-president is Robert Hilton, vice-president of the Ault & Wiborg Co., Cincinnati, Ohio. Henry A. Datter has been chosen secretary.

The new concern will continue the business of the old firm and will enlarge its selling staff for the continuation of the sole selling agency for the dyestuffs, intermediates and chemicals manufactured by the Ault & Wiborg Co. The principal offices of the new corporation will be at Cedar and Washington streets, New York City, with branch offices at Boston, Philadelphia and Columbus, Ga.

A PORTABLE APPARATUS AND SIMPLE METHOD FOR DETERMINING SO_2

Adapted for the Use of Engineers in Mine Examination Work*

By G. W. JONES, J. H. CAPPS and S. H. KATZ

Introduction.

The engineers of the Bureau of Mines have had need for a method for determining the amount of sulphur dioxide in the air of sulphide mineral mines, especially in case of fires. The requirements were an apparatus of strong, cheap and readily replaceable parts, easily portable, and readily workable by the average engineer. With these ideas in mind the method herein described was developed. No especial originality is claimed for it. Similar processes have been used by others for a long time. However, it is believed that this adaptation can be used to advantage in the particular field for which it was planned. During the experiments observations of the effect on the senses of sulphur dioxide gas in various concentrations were also recorded.

The work described herein forms part of a partially completed study of sulphur dioxide which will be published by the Bureau of Mines.

Apparatus.

The main apparatus, pictured in *Figure* 1, consisted of two 2½ liter aspirating bottles with tubulars joined by a rubber tube, clamped with pinch cock. One bottle was completely filled with acidified water to be described later. This bottle was closed with a two-holed rubber stopper. Through one hole was run a 100 cc. separatory funnel with a stem of 1 mm. bore. The top of the funnel was closed by a one-holed rubber stopper glass capillary tube, rubber tube and pinch cock. Through the other hole of the rubber stopper extended one arm of a three-way cock. This arm was bent into U form, for the purpose of directing the incoming stream of gas against the rubber stopper so as to break it up and prevent contact of gas and water as much as possible. The other bottle was closed with a one-holed rubber stopper holding a guard tube. This was filled with soda lime with one inch of cotton wool on top for a filter. The guard tube was closed by a one-holed rubber stopper glass tube and rubber tube with pinch cock.

This apparatus, together with its accessories, were carried in the case shown in *Plate* 1, designed for portability and accessibility. The accessories consisted of five bottles of reagents, to be described hereafter, a 50 cc. graduated cylinder with divisions 0.2 cc. apart, two long glass tubes, and a rubber bulb handpump with rubber tubing attached. The tubes and pump were for use in securing samples. An extra guard tube containing soda lime was provided for use in some special cases.

The outfit and case complete measured 10½x20½x23 inches and weighed 55 lbs.

Solutions.

Aspirating Liquid—

The liquid used to aspirate the sample into the bottle is the purest drinking water, readily available at the place where analyses are to be made. Since such waters vary in alkalinity and other properties which might affect the results, 10 cc. of the sulphuric acid are added to the 2,600 cc. of water needed. The 10 cc. of starch solution are added to serve as indicator.

Plate 1—Case containing apparatus and chemicals for determining sulphur dioxide.

Starch Solution—

250 cc. of starch solution were provided. This was made by mixing 50 grams of starch to a paste with

---

*Published by permission of the Director of the Bureau of Mines.

cold distilled water, diluting to 50 cc. with distilled water, boiling a few minutes, stirring meanwhile, then diluting to one liter with 500 cc. of distilled water containing 2 grams of potassium iodide, and adding a few drops of chloroform as preservative.

Thiosulphate Solution—

250 cc. were provided. The strength was roughly one-fortieth normal.

Sulphuric Acid—

A bottle containing 250 cc. of chemically pure sulphuric acid, of 1.84 specific gravity, provided.

Distilled Water—

One liter provided. This needs no description.

Iodine Solution—

One liter of iodine solution provided. This was approximately 5/100 normal, accurately standardized with arsenic trioxide. One cc. was roughly equivalent to .02% of SO_2 when used in the apparatus.

Preliminary Operations.

Before taking a sample, a few cc. of the iodine solution are poured into the separatory funnel and shaken to wet the walls. All the water in the aspirating bottles is then titrated to the first distinct blue color. Trial during the preliminary work with this method showed that one to two drops of the solution were sufficient to change the liquid from colorless to blue when the point of change had been reached. The point where the change occurs should be closely observed, and this amount for the actual color change should not be exceeded. In case the end point is overrun, a few drops of the thiosulphate solution may be added till colorless and the iodine titration repeated till the exact end point is found.

When the aspirating solution is titrated to the point of color change, the excess iodine is wasted onto the ground by allowing it to drain from the separatory funnel through the capillary tube for one-half minute.

Taking the Samples.

Two conditions may confront the operator in securing the samples: In the one case the operator is standing in the atmosphere which is to be analyzed. Here the method of sampling is obvious. In the other case, the sample is to be taken from behind a wall or brattice.

In case the sample must be taken from behind a brattice, an opening is first to be provided. The rubber tube attached to the intake end of the handpump is attached to a glass tube and the glass tube pushed through the opening. The end of the tube should extend at least a foot beyond the inside wall. The excess opening in the brattice should then be stopped with moist earth or a handkerchief. The rubber tube on the discharge end of the handpump is slipped over the tube and the cock turned so as to pump into the outside air. The pump should be worked about three minutes, till the gas from behind the brattice fills all the tubes. Then the cock is turned so as to connect with the interior of the bottle.

The sample bottle is held about three feet above the other to allow rapid transference of the water. On trial, about 45 seconds were required for this. The bottom of the bottle should be held level and as much water allowed to flow out in this position as will. Calibration showed 2,500 c.c. plus 10 c.c. to be the volume of gas sucked into the bottle under these conditions.

Determination of Sulfur Dioxide.

When the sample is secured, 50 c.c. of iodine solution, measured in the graduated cylinder, are poured into the separatory funnel and the rubber stopper replaced in the funnel. When handling the iodine solution in an atmosphere containing sulfur dioxide, it must be borne in mind that the atmosphere acts upon the reagent. Hence it should be protected as much as possible and handled rapidly when exposed. The free end of the small rubber tube connecting with the separatory funnel is taken between the teeth of the operator, the pinch cock let down till the tube ran through the circle, pressure is blown upon the iodine solution as desired and the tube pinched shut with the teeth. The titration is now made, during which the pressure on the iodine solution is increased or decreased as needed. During the titration, the bottle is vigorously shaken so as to rinse all parts of the walls with the solution in the bottom. When the endpoint is established, half the displacing liquid is allowed to run back into the titrating bottle. When the surrounding atmosphere contains sulfur dioxide, this should be done rather slowly, the bottles being on the same level and the guard tube being securely in place and its clamp opened. The water in the titrating bottle is then again titrated to the endpoint, after which the rubber stopper holding the separatory funnel is transferred to the other bottle and the other half of the water solution titrated to the exact endpoint. This completes the titration.

The residual iodine solution is run into the graduate, allowed to drain half a minute and the volume read. The difference between this and the original volume is the volume used in titrating.

In case the determination must be made in an atmosphere where breathing apparatus is necessary, the pressure on the iodine solution in the separatory funnel may be made by means of the handpump and retained by means of the pinch cock. In this case the extra guard tube of soda lime should be inserted between the funnel and the pump.

When less than 5 c.c. of the iodine solution are needed to make a titration it has been found best to repeat the experiment with a more dilute iodine solution. The funnel is rinsed with distilled water and drained. 5 c.c. of the iodine solution are measured into the graduate and distilled waste added to the 50 c.c. mark. The solution is thoroughly mixed, poured into the separatory funnel and the experiment repeated. Trial showed that a distinct endpoint could be established in a dark room by the light of a flashlight with five drops or less of this dilute solution.

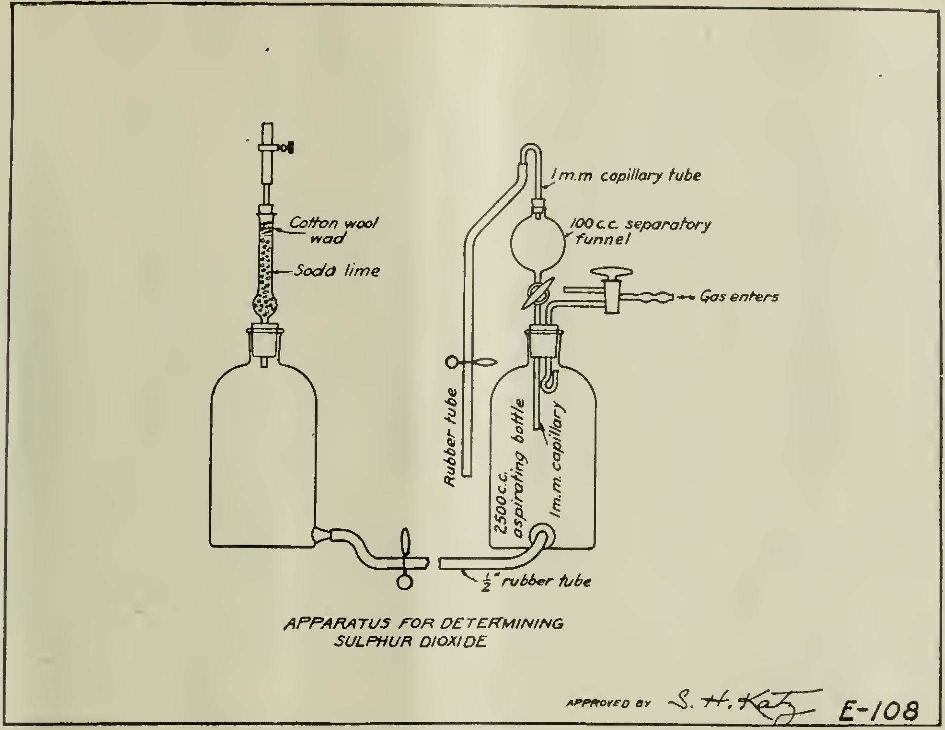

Figure 1—Apparatus for determining sulphur dioxide in air.

Calculation of Percentage of Sulfur Dioxide.

The iodine solution should be standardized to read cubic centimeters of sulfur dioxide at 760 m.m. and 0° C. Changes in barometric pressure and the temperature would affect the determinations, and for that reason must be taken into account in making the calculations. Standard conditions of 760 m.m. barometric pressure and 0° C. temperature should be the basis for comparison of all analyses. *Figure* 3 is a graph of factors to be used to reduce observed percentages to those at the standard conditions. An example will show how these are to be used:

11 c.c. of iodine solution were used to titrate the SO_2 in a sample, the barometer stood at 720 m.m. and the temperature was 15° C., 1 c.c. of the iodine solution was equivalent to .4327 c.c. of sulfur dioxide gas at standard conditions. What was the percentage of sulfur dioxide in the gas when reduced to standard conditions?

$.4327 \times 11 = 4.76$ c.c. SO_2 at standard conditions were in the sample.

$$\frac{4.76}{(2{,}500 = \text{vol. in analyzing bottle})} \times 100 = .1904 \left\{ \begin{array}{l} \text{Apparent per-} \\ \text{centage of } SO_2 \end{array} \right.$$

1.55 is factor for 720 m.m. from graph.

1.055 is factor for 15° C. from graph.

$.1904 \times 1.055 \times 1.055 = .21\%$ SO_2 at standard conditions.

In doing the work, recording data and making calculations it is best to carry through three significant figures. Then cut those beyond the nearest second significant figure when the calculation is completed. When the percentage of sulfur dioxide is below 1%, no accuracy beyond the two figures can be claimed for the method.

It is obvious that the calculations can be shortened when one set of apparatus and solutions are used continuously for analyses, by means of factors common to all calculations.

Tests of the Method.

To determine the efficacy of the method, a room was filled with an atmosphere containing sulfur dioxide by burning sulfur. Two electric fans were operated in it continuously so as to produce uniform composition. At the time that the samples were taken into the apparatus, another sample was taken by the standard vacuum tube method of the Bureau of Mines.* This sample was later analyzed with a Haldane apparatus. With this apparatus, the total gases absorbed by potassium hydroxide were found. From the percentage of total alkali soluble gases .03% was subtracted for the carbon dioxide. The remainder was sulfur dioxide.

Table 1 gives the results of these tests.

---

*The fraction expressions with 5 in the denominator mean that the Iodine Solution was diluted 1 to 5 with distilled waters. †Figures were interpolated, not determined.

In tests 18 to 26, *Table* 1, the concentration of sulphur dioxide was too low to be determined by the laboratory method. But the changes of concentration, as indicated by the iodine method, with time, were recorded for these tests and the previous ones, beginning with No. 15. These are plotted in *Figure* 2. It is seen that the change with time of the concentration of the sulfur dioxide in the room forms a smooth curve of the kind to be expected.

Other tests of the method throughout its entire range were made by analyzing synthetic mixtures of air and sulfur dioxide of known composition. The results are given in *Table* 2.

The errors of measurement in forming the synthetic mixtures were as large or larger than those from the iodine determination. The results of this table indicate not the absolute accuracy of the method but rather the fact that it may be depended upon to indicate sulfur dioxide in air from a minimum of a few parts per million to a per cent or more.

Table 1 shows the accuracy better. The method is fully as accurate as the most precise gasometric laboratory methods within the range of the laboratory apparatus; furthermore, it has a range extending down to a lower limit of about ten parts per million parts of gas. Though the range extends from this

low figure of sulfur dioxide to many thousand parts per million, it may be considered accurate only to two significant figures except in the higher ranges.

Effects of Various Proportions of Sulfur Dioxide in Air on the Senses.

During the experiments in the room containing sulfur dioxide it was necessary to wear breathing apparatus of the type used for mine rescue purposes, in all but the lower concentrations. The apparatus had a mouthpiece for breathing and soft rubber edged goggles which readily conform to and fit the face, for protecting the eyes. The rubber part of the goggles was wet and carefully adjusted to secure accurate fitting. The utmost care was necessary to have perfect adjustment, especially in the higher concentrations of sulfur dioxide. If such care was not taken the gas penetrated to the eyes, producing pain and blindness, which made it entirely impossible to work.

The observations which were made during the tests are arranged in order of increasing concentration of sulfur dioxide in *Table* 3.

By referring to this table an estimate of the proportion of sulfur dioxide in air may be made by an observer without the use of analysis. And estimates may even be made for concentration lower than those investigated. The lowest concentration of sulfur dioxide tested by analysis was about 40 parts per million. At this concentration the air had a biting effect on the mucus of the nose. Undoubtedly at one-tenth of this concentration or four parts per million sulfur dioxide would have a distinct odor.

Other Uses for the Apparatus

Although experiments were not made with other gases which may be determined by means of iodimetry,

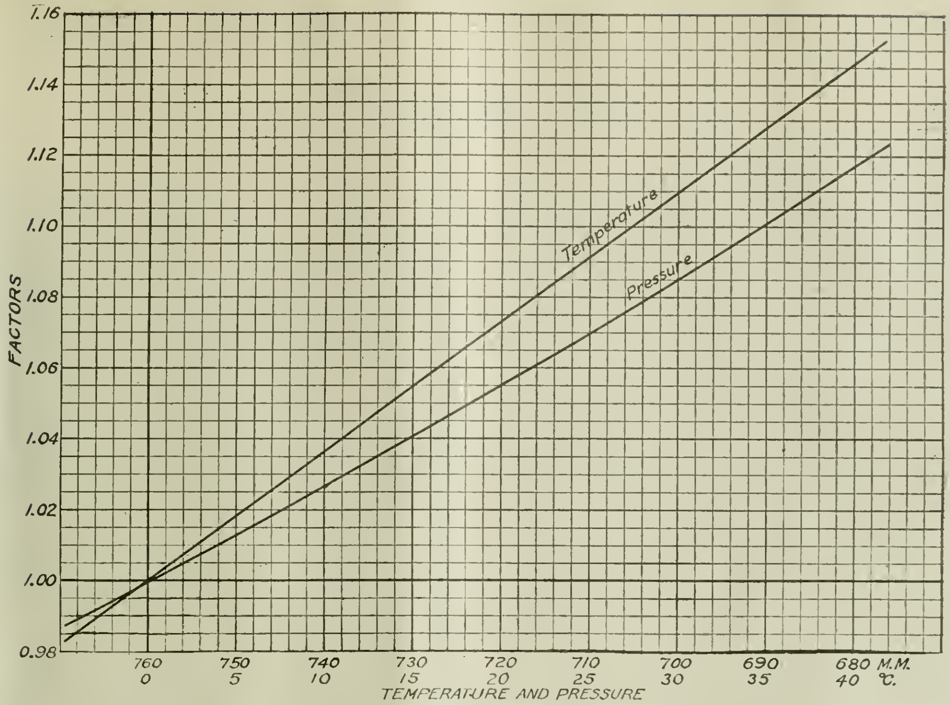

Figure 3—Curves of factors for reducing observed percentages of sulphur dioxide to those at standard conditions.

the apparatus may be used to determine such gases as hydrogen sulphide, chlorine, oxides of nitrogen and some others as well as sulfur dioxide. In the case of the latter two, iodine would be liberated in the water solution which should contain some potassium iodide. The starch-iodine blue solution would then be titrated to colorless by means of a standard sodium thiosulfate solution.

Summary.

A method and apparatus for determination of sulfur dioxide by means of the iodine titration has been developed for the use of engineers working in the field. The apparatus is strong, cheap, easily replaceable and assembled into a case designed for portability. The method is not accurate beyond two significant figures, but has a range from about ten parts per million by volume to one per cent. or more.

Observations of the effect of sulfur dioxide on the senses have been made and arranged in tabular form. With this it is possible to roughly estimate the small proportions of sulfur dioxide without analysis.

To Manufacture Chemicals.

To engage in the manufacture of chemicals and allied products the Allen Mfg. Co. has been incorporated with a capital of $10,000 at Quakertown, N. J., by Harry W. Haver, Walter A. Allen, Harry M. Oakes and George E. Rose.

Additional Plans for Fourth National Chemical Show

In its latest bulletin, the management of the Chemical Exposition has announced for the benefit of exhibitors and others interested that the rumored Government plans for taking over the Grand Central Palace for war purposes will in no wise affect the holding of this event according to schedule.

Present indications are that the Fourth National Exposition of Chemical Industries, to be held in Grand Central Palace, New York, September 23 to 28, will be the greatest exhibition of its kind ever held. Preparations for this gigantic exhibition are well under way and the advisory committee is working hard to make every department of the affair a success.

Some sections of the South again are sending exhibits, and Canada is taking the opportunity of presenting the materials it has available for development by the chemist and financier. Technical and business men over the country should give heed to these exhibits, since they will show how they can meet the war-time need. A section for the glass and ceramic industry has been added with which the American Ceramic Society is co-operating.

Men prominent in the chemical and allied industries will speak on subjects vital to present condi-

(*Continued on page 348*)

NEW SOURCES OF FERTILIZING ELEMENTS

Something of the romance atached to the recent feverish search for new fertilizing materials which followed the shutting off of our supply of potash from the mines of Stassfurt in 1914, is told by William H. Ross, of the U. S. Department of Agriculture, who indicates in his recital, the splendid ability of our industrial chemists when suddenly called upon to cope with the difficult situation.

In describing his search for new sources of fertilizing elements, Mr. Ross points to a striking illustration of the change in value which a product may undergo in the utilization of certain woods, as the oak and the hemlock. In the early development of the country the barks of these trees was the only source of tannin for the manufacture of leather. In many places the collection of bark brought profits that greatly exceeded those obtained from the remainder of the tree, which was allowed to decay or destroyed in clearing the land.

At present the demand for wood products is much greater than the supply. All tops of trees, slabs, edgings, and the sawdust in particular are used for different purposes, as when destructively distilled for the preparation of many chemical products, as alcohol, sugar, and oxalic acid. The residue in this case, as well as when the wood is used for fuel, becomes directly available for use as potash fertilizer, of which the hardwood wastes of the country produces about 19,000 tons annually. The importance of this supply has been greatly emphasized since the war has cut off the principal source of this greatly needed material.

An industry that thrives more than any other on the utilization of waste is the preparation of meat products. Pork, beef and mutton represent only from 40 to 85 per cent. of the animal on the hoof. Time was when a large part of the remaining 15 to 60 per cent was thrown away. At present practically all the profits of this industry are derived from their successful exploitation.

The by-products obtained in the packing house industry may be divided into two classes—the edible and the inedible. The inedible constitute the external covering (hair, horns, hoofs and hides), some of the offal, and the bones. From these are prepared a great variety of substances, some of which have developed into enormous industries in themselves, such as leather, soap, glue and fertilizer. The last mentioned represents the ultimate utilization of packing house waste. For example, in the manufacture of buttons, combs, knife handles and spatulas from the horns and hoofs of cattle and sheep and the hoofs of hogs, the waste resulting from the preparation of these articles was at one time thrown away, but it has been found that by treating such material with sulphuric acid the nitrogen which it contains becomes available as a fertilizer.

Under the trade name of processed fertilizer this waste from a waste is thus profitably disposed of. The trimmings and waste in the manufacture of hair and leather goods are likewise consumed as fertilizer.

Of more importance to fertilizer manufacture is the utilization of the bones, blood, entrails, etc. Incongruous as it may seem, each of these materials is now used in the preparation of a great many different products. Thus the bones may be steamed, ground, and placed on the market under the name of bone meal, or treated with sulphuric acid to make them even more readily available for plant food.

The blood, entrails and other miscellaneous material all find ultimate disposal in what is known as tankage in the fertilizer trade, so valuable for their nitrogen and phosphoric acid content.

The oldest industry to make use of waste for fertilizing is the fish industry. The custom of fertilizing crops with fish existed among the Indians of New England before the arrival of white settlers. It is said that for fertilizing corn one or two fish were buried in each hill. This procedure was adopted by the colonists, and at the time of a large catch the surplus fish were simply spread broadcast over the fields. In places where fish were plentiful this disposal of an over-supply of fish has been practiced until very recent times.

It was soon observed, however, that the response first noted on liberally fertilizing with fish decreased, and the initial good effects could be obtained again only after the soil had been allowed to stand for a time without further applications of fish. This was finally shown to be due to the action on plants of the oil in the fish. When the oil was removed by cooking and pressing the residue no longer caused ill effects and its value as a fertilizer was greatly improved. At present crude fish oil is normally quoted as about 25 cents per gallon, which more than covers the cost of extraction. It thus happens that in the utilization of fish waste the recovery of the extracted residue, or fish scrap, as it is known in the trade, often becomes subordinate to the recovery of the oil.

The principal sources of fish oil and scrap are nonedibile fish, as the menhaden, and the refuse collected in canning factories from the heads, tails, bones, shells, intestines, etc., of edible fish. Non-edible fish furnish the largest supply. The average annual catch of menhaden for the last eight years was about 500,000,000 fish, which, with the refuse collected in canneries, produced about 60,000 tons of scrap and 85,000 barrels of oil. The largest recorded catch was in 1903, when about 1,000,000,000 fish were caught.

Generally speaking, fish scrap contains about 8 per cent. each of nitrogen and phosphoric acid. The presence in fish scrap of a comparatively high percentage of two of the essential plant foods makes it one of the most valuable of the organic fertilizers.

America's largest manufacturing industry is iron and steel. The pig iron recovered in smelting iron ore amounts to about 25 per cent. of the raw materials. The equivalent of about 14 per cent. is driven off by volatilization in the cooking of the coal; in the process of smelting a further 40 per cent. escapes in gas, fume and dust; and the remaining 21 per cent. represents the slag.

In the early history of the industry little was done to utilize any of these wastes. In fact, until the last decade the most that was done was to utilize to some extent the heat from the furnace. Recently, however, much attention has been given to the utilization of waste, and more advance has been made in the efficient operation of the blast furnace than, perhaps, in any other industry.

In 1909 84 per cent. of the coke in the country was prepared in beehive ovens and the remaining 16 per cent. in by-product ovens. In 1916 the output of by-product coke increased to 38.6 per cent. of the total, with every prospect of a still further increase. In the by-product oven there is recovered not only the nitrogen in the coal but a great number of other by-products, which find very extensive application in the manufacture of dyes, explosives, drugs and other products. In this process the nitrogen is recovered as ammonia. By combining this with sulphuric acid ammonia sulphate is formed, which is one of the most important sources of nitrogenous fertilizers. The output in 1915 amounted to 249,000 tons, and in 1916, to 325,000, valued at about $25,000,000.

The economic uses of blast-furnace slag have also been greatly developed the last few years. Formerly this was an incumbrance and its disposal was often a matter of considerable expense. Of much more value as fertilizer is the slag obtained in the preparation of steel from high phosphorus pig iron. To remove the excess of phosphorus the iron is melted in converters lined with limestone, and quicklime is added. At a certain stage air is driven through the molten material, which leads to an accumulation in the slag of the phosphorus originally present in the metal. This slag is drawn off and cooled, and when finely ground is placed on the market under the trade name of basic slag. The phosphoric acid in the slag prepared in this way varies from 11 to 23 per cent.

For a long time the fertilizing value of the slag was not recognized, but it has now become one of the most popular of commercial fertilizers. In fact, on account of its freedom from acidity many prefer it to any other phosphatic material. The slag produced for the fertilizer trade amounts to about 2,000,000 tons annually.

The third main avenue for escape of waste in the blast furnace is volatilization. These losses in the form of gas, dust and fume are receiving special attention at present. In the operation of the modern blast furnace a portion of the waste gases is utilized directly in gas engines for making a blast or for generating electric power, while the remainder is used in burning under boilers and in heating stoves for preheating the blast. The dust collected in the stoves and boilers has long been known to have some fertilizing value, but little attention was given to it until recently, when it was found that the dust collected in some plants contains sometimes upward of 20 per cent. of soluble potash, of great value for use in fertilizers.

In an investigation recently made at one of the steel plants of this country it has been found that the potash in the dust collected in the stoves and boilers amounts to only about 5 per cent. of the total escaping from the furnace. The greater part is still lost in the washers or escapes from the flues. Tests also were made at the same plant with an electrostatic or hot dry process for purifying the gas. The results showed not only potash but other materials, as iron and zinc compounds, which may be carried over in the dust. The possibilities of potash recovery in the steel industry are promising, but, owing to the abnormal condition now prevailing, new developments are likely to be postponed for the present.

A good illustration of a case in which a valuable product is lost in an industry without it being known for a long time that a waste is actually taking place is furnished by the escape of potash from cement plants. In the manufacture of Portland cement an intimate mixture of a material like clay and limestone is heated to the point of fusion. For many years it was thought that in the manufacture of cement this product was the only one produced, and that, therefore, no loss of any other material took place. It is now known, however, that in the burning of cement the potash in the raw materials escapes from the kilns with the flue dust. Even after it was noticed that some loss of potash took place in this way, little importance was attached to the observation until analyses were made four or five years ago of dust collected at the plant of the Riverside Portland Cement Company.

The original object of collecting the dust was to comply with injunction proceedings instituted by orange growers against the escape of dust from the plant. To the surprise of every one the dust when collected was found to contain such a percentage of potash as to make its recovery a profitable procedure entirely apart from any other consideration. Since then a number of additional plants have also installed equipment for collecting potash, and at several other plants installations are now building.

The recovery of potash at the Riverside plant now

(*Concluded on page 340*)

The Estimation of Potash

By BERTRAM BLOUNT, F. I. C.*

Potash is now a material of national interest, and its estimation with accuracy is the root of the whole matter. Such things as felspar, blast-furnace flue dust, the dust from cement kilns were commonly disregarded as potential sources of potash, but the stern necessities of war have taught us to be no longer dependent on the Stassfurt deposits. Usually analyses of silicate rocks, clays, cements, and the like have hitherto ended with "alkalis and loss" or "perte et divers," both phrases quite sufficient for the purpose in view. And here I may remark that of the many thousands of analyses of such materials published by German chemists there is hardly one which does not say "alkalis so much per cent"—which, of course, is impossible unless the mixed oxides are isolated and weighed as such. If weighed jointly as sulphate, as is often done, no such return is possible, and if they are computed by estimating the sulphuric anhydride, then they should be stated separately.

With soluble materials containing potash there is little difficulty save in the later stages of the process, but in the case of the substances cited above some complications may arise.

Substances containing potash in a soluble form can be leached out and the potash estimated in the usual way. What potash can be regarded as soluble has to be decided by an arbitrary method; it is generally agreed that the citric acid process is suitable. But, as in the case of basic slag, the material may be available, although not immediately soluble.

Therefore it comes to this: That the whole of the potash in whatever form in any substance shall be estimated. Such a method is on a par with the absolute method of Dumas for nitrogen. All that is needed is the potash—as in the Dumas case, the nitrogen.

Taking, then, a general basis, it may be said that the sound principle of eliminating everything from the substance analysed, except the substance to be determined, must be adopted. Everything must be cleared out. Shortcuts, useful for particular purposes, are practically useless in this case. Blank tests must be made throughout, and analyses of mixtures containing a known amount of potash are desirable. The method used in my laboratory is as follows:

Method of the Estimation of Potash in Siliceous Rocks, Clays, etc.

Opening Up.—It is essential that the whole of the material should be in solution, and for this purpose many different methods have been suggested, such as that by Lawrence Smith. In practice, however, I have found that treatment by hydrofluoric acid, together with sulphuric acid, is by far the most accurate and satisfactory method.

The method which I have adopted is as follows: A small portion of the bulk ground sample is very finely ground in an agate mortar, and if necessary dried again. One-half a grm. to 2 grms. is weighed out and transferred to a fair-sized platinum crucible, and digested for two or three hours with 10 cc. purest hydrofluoric acid (that supplied in cerasin bottle) and 2 cc. sulphuric acid (*puriss.*). If necessary, a further 10 cc. of hydrofluoric acid is added, and the whole gently evaporated till most of the sulphuric acid has been fumed off, great care being taken to prevent loss by "spurting." The anhydrous sulphates are taken up by digesting with hydrochloric acid, and the diluted solution filtered off through a small filter, retaining the insoluble matter in the dish. This is further digested with hydrochloric acid and filtered off as before, and if any residue still remains, which is usually due to insufficient attack, it is washed on to the filter-paper, which is then thoroughly washed, dried, very gently ignited in a platinum crucible, and the above process of treatment with hydrofluoric acid, etc., repeated. The original grinding in the agate should be so thorough that further grinding at this stage should be unnecessary, as it would involve loss. In the case of materials such as limestone, etc., the bulk of which can be readily dissolved, the method is modified, in that the material is first digested with hydrochloric acid, and the insoluble portion is then treated as above and aided to the main solution.

Removing Other Constituents.—The iron, alumina, and manganese are removed by the addition of bromine and ammonia and a short digestion. The precipitate is filtered off and thoroughly washed. Ammonia is added to the filtrate and the whole boiled. Ammonium oxalate is then added and the whole boiled up again. After the precipitate has been allowed to settle, the calcium oxalate is filtered off and washed thoroughly, and the filtrate gently evaporated to a low bulk. The basin is then covered and sufficient nitric acid is added to destroy the ammonium salts, and, whilst still covered, the whole is evaporated till just dry, or till fumes of sulphuric acid appear. After cooling, the residue is taken up in 2 or 3 cc. of hydrochloric acid and a little water, and gently evaporated to low bulk. The solution is diluted, a small excess of a clear solution of barium hydrate is added, and the whole digested for about half-an-hour, during which time a slight skin of barium carbonate should form on top,

---

*From the *Chemical News*.

showing that an excess is present. The precipitate is filtered off and thoroughly washed, and the filtrate digested with excess of ammonium carbonate, and the precipitated barium carbonate filtered off and washed. The filtrate is evaporated to low bulk on a water-bath, a few cc. of hydrochloric acid are cautiously added, and the whole transferred to a small platinum dish and evaporated to dryness on a water-bath. The residue is very gently ignited over an argand burner to drive off all the ammonium chloride, the crude alkali chlorides dissolved in a small quantity of water, a drop or two of ammonium carbonate added, and digested for a minute or two, and the whole filtered off through a very small filter with thorough washing into a weighed platinum dish. The filtrate is evaporated on a water-bath and the residue carefully ignited over an argand, cooled in a desiccator, and weighed. This is the weight of the pure alkali chlorides.

As potash adheres very persistently to all the precipitates and filter-papers, it is absolutely essential that the washings should be very thorough at all the various stages. It is better to have to remove traces of any slightly soluble precipitate such as magnesia from the crude alkali chlorides than to run the risk of leaving some of the potash in the precipitates or filter-papers.

Separation of Potassium from Sodium.—Although many methods have been tried, such as the cobaltinitrite and perchlorate methods, the older method of platinic chloride still seems the best where accuracy is required. The pure alkali chlorides, obtained as above, are dissolved in a small quantity of water (and should, of course, leave no residue) and sufficient platinic chloride added to combine with the whole of the potassium and sodium salts and leave a slight excess. The solution is evaporated on the water-bath till it begins to get pasty, then cooled, diluted with a sufficient quantity of 80 per cent. alcohol by volume to take up the whole of the sodium salt, and allowed to stand for a few hours. If the quantity of alkali is large, it is better to take up the pasty chlorides in a small measured quantity of hot water, cool, and add sufficient absolute alcohol to bring the final solution to 80 per cent. by volume.

The precipitate of potassium platinic chloride is filtered off, washed with 80 per cent. alcohol till quite free from sodium salts, warmed to drive off the alcohol, and then dissolved through into a weighed platinum dish by means of boiling water, evaporated to dryness, dried in an air-oven, cooled, and weighed.

Platinum Residues.—Many methods have been published, reference to some of which is given below.

The best and shortest way is to take the whole mass to dryness and ignite to full redness (1100° C.). The mass is ground finely and extracted with water, then with hydrochloric acid, washed well, and then extracted with nitric acid. The residue is again ignited and extracted with aqua regia. The solution is evaporated to dryness and taken up with HCl and water.

All solutions except the first aqueous extract are returned to be worked up with the next batch.

Addendum.—On account of the scarcity of platinum it is advisable to have an alternative method. The best of these is the perchlorate process, and a good account is given by Mellor in "A Treatise on Quantitative Inorganic Analysis," p. 237, which is here transcribed.

The Process.—"Dissolve the mixed chlorides (see Note) in from 10 to 15 cc. of hot water, and then add two or three times as much perchloric acid as is theoretically required to precipitate the mixed perchlorates. Evaporate the mixture on a water-bath to a syrupy liquid until the fumes of perchloric begin to appear; cool a little. Take up the mass with hot water, and add 5 to 6 cc. of perchloric acid. Re-evaporate until the fumes of perchloric acid again begin to appear. The object of this treatment is to remove the hydrochloric acid. This is important. Stir the cold mass with about 20 cc. of 96 to 97 per cent. alcohol containing 0.2 per cent. by weight of perchloric acid. Keep the potassium perchlorate as coarsely granular as possible. Let settle. Decant through a dried and weighed Gooch's crucible. Wash the residue by decantation through the Gooch's crucible three times. About 20 cc. of the alcohol will be needed for the washing. Transfer the precipitate to the Gooch's crucible by means of alcohol. Some prefer to wash the residue at this stage with 20 cc. of a mixture of equal parts of 97 per cent. alcohol and ether. Dry the precipitate at 120—130° for about half-an-hour, and then weigh as $KClO_4$."

(Note.—The amount is calculated as follows: Assume that the mixed chlorides are all sodium chloride, and that the perchloric acid used is 30 per cent. (sp. gr. 1.20) solution). Multiply the weight of the mixed chlorides by 6, and the product represents the number of cc. of acid required for the work. Perchloric acid of approximately 60 per cent. strength has a sp. gr. of 1.54; 30 per cent., 1.20; and 20 per cent., 1.12. There is no difficulty about keeping the acid. It is not decomposed by hydrochloric or by sulphurous acid. The acid slowly volatilises at 138° C. without decomposition. It is not affected by exposure to light. The strength of the acid is easily determined by titration of a known amount with standard sodium hydroxide with phenolphthaleïn as indicator.)

The process given in the main paper is followed strictly until the mixed chlorides are isolated in a pure state. They are then separated by the perchlorate method instead of by the use of platinic chloride. In other respects the operations are identical.

The Nomenclature Used in Colloid Chemistry—A Plea for Reform

By ARTHUR W. THOMAS[*]

Colloid chemistry is no longer considered as a mere collection of mysterious substances and "abnormal" reactions. It is an important branch of chemical and physical science possessing a fairly well established working basis and is rapidly acquiring new students.

It suffers, however, like all virgin sciences, the affliction of superfluity of terms used to describe essentially the same things, careless and loose use of some expressions, and confusion of nomenclature in general. This condition results in a great handicap to new students. It is very difficult for them to acquire clear conceptions from their first readings of the various works on the subject.

It is time that this matter be taken in hand by some committee of our Chemical Society for the purpose of removing this needless handicap and confusion by defining the various terms used in colloid science, eliminating unnecessary ones and by standardization of the terminology in general, just as was done with the terminology of the proteins by the biological chemists some years ago.

The paragraphs which follow attempt to point out some of the cases of malusage of terms.

Colloidal Solution Defined.

No objection can be raised against the word "colloid." It is distinctive, but the use of the expression "colloidal *solution*" is to be strongly condemned, since it is so evident that substances in the colloidal condition are not dissolved, in the strict sense of the term. Colloidal particles are in a condition midway between solution and mechanical suspension, and they are held in this peculiar state of *dispersion* by virtue of their surface energy, electrical charge, their kinetic energy as manifested by the Brownian movement, and the adsorbed ions of electrolytes which are essential to the stability of all colloids.

The general term "dispersion," as suggested by Wo. Ostwald, is to be preferred to the special term "solution," *e. g.*,

"Mechanical suspensions" are coarse dispersions.
"Colloidal solutions" are colloidal dispersions, and
"True solutions" are molecular dispersions.

The particles, or "internal phase" of these systems are known as the "dispersed phase," and the liquid in which they are dispersed, the external phase, is known as the "dispersion medium."

The present usage of the word "sol' and of its modifications—"hydrosol," "alcosol," etc., to describe a colloidal dispersion, is the same as that of Graham, their originator. I have noticed, however, that the word "sol" has been used by a few writers in the sense of the dispersed phase, *i. e.,* the particles in colloidal dispersion. Is this use of the term to be permitted? Graham invented it as a short and convenient substitute for colloidal "solution" and a perusal of the works by Bechhold, Cassuto, Freundlich, Hatchek, Ostwald, Taylor and Zsigmondy shows that the original sense of the expression has been retained by these writers.

Use of the Term "Gel."

The use of the term "gel," however, and of its modifications, "hydrogel," "alcogel," etc., is deplorably loose and confusing. This term was coined by Graham[1] and first used by him in discussing the "pectization" or coagulation of the hydrosol of silicic acid. Therefore, if we are to limit the use of "gel' to its original sense, we should use it only when speaking of the definite *coagula* of sols. This is not the case, however. Any substance which resembles a jelly in appearance is called "gel," although in chemical and physical properties it may be entirely different from the kind of matter which Graham had in mind when he invented the term. This use of the expression is exceedingly popular and would be very difficult to overcome.

Let us take up a case or two to show how unscientific this latter usage of the term is. For example, consider the dissolution or dispersion of gelatine in hot water. It forms a very mobile "solution" or rather dispersion, and in this form is called a hydrosol or sol. If this hydrosol be allowed to cool, it becomes very viscous and "sets" to a jelly-like mass. In this stiffened form it is popularly known as a "hydrogel" or "gel." If it be warmed again its viscosity decreases, it becomes mobile and is called a "sol." Now if this use of the term "gel" (which is not as Graham intended) is to be permitted, then what is the line of demarcation between the sol and gel states? A change in state has occurred, it is true, for in the sol condition the water was the external phase whereas in the so-called gel state the gelatine became the external phase and the water internal. The change is very gradual, however, and our change of terms to suit the change in appearance of the system is exceedingly arbitrary and unscientific. Furthermore no chemical change in the nature of the gelatine has taken place.

If some alum or a trace of mercuric chloride be added to the gelatin hydrosol, a coagulum is obtained which is correctly termed a gel according to Graham.

---

[*] Department of Chemistry, Columbia University. From the Journal of the American Leather Chemists' Association.

This is a coagulated compound, however, a chemical reaction has taken place. It will not redissolve in water and is, therefore, entirely different from the case discussed above, which is also commonly called gel.

To further complicate matters, the dry pieces of gelatine (and in fact any other colloid which will "dissolve" readily) which were used to make the original sol are also quite commonly called "gel.' Lottermoser called attention to this several years ago and suggested that such pieces of gelatine, or of any other dry "soluble" colloid be called "solid sol." This suggestion is obviously bad. Why apply any special term at all?

When a hydrous ferric oxide sol is allowed to evaporate spontaneously, it will go through a jelly-like stage and finally become a hard scaly residue when all or nearly all of the water has left it. The jelly-like form will redisperse when warmed with an excess of water, while the amorphous form will not. Yet both forms are called "gel!" Zsigmondy distinguishes between these two different forms by calling the first one "hydrogel" and the second, "gel."

A review of the texts on colloidal chemistry shows the following conceptions of this term.

Cassuto[2] calls a gel the gelatinous precipitate obtained from a sol by means of an electrolyte, heat or evaporation; *i. e.*, a gel is formed by coagulation of a sol. He calls stiffened sols (or jellies), "gelatines."

Bechold[3] remarks the loose use of the word "gel" and states that he restricts it to the description of the coagula from sols. To the stiffened sols or jellies he applies the term "Gallerte," which in English might be called "jelly."

Freundlich[4] says that systems of solid dispersion media and liquid dispersed phase are gels as distinguished from the reverse which are suspensions or emulsions. In other words he applies the word "gel" to jellies.

Hatschek[5] refers to the fact that Graham applied the name "gels" to the products obtained by the coagulation of sols, but later on in his book he calls jellies, gels also.

Ostwald in his "Handbook of Colloid Chemistry," considers all colloids as gels when the system becomes "microscopically heterogeneous." That is to say, he applies the term promiscuously.

Taylor[6] uses "gel" in the same loose general manner as Ostwald, Hatschek and Freundlich.

Zsigmondy in his "Kolloidchemie," limits the word "gel" to the dry residue which will not redisperse in a solvent, but he applies "hydrogel" to the jelly-like mass formed by removal of the dispersion medium or by salt coagulation.

Hardy[7] recognized the difference in properties of substances called "gels" and he qualified the term—"gels by coagulation" and "gels by stiffening."

I feel confident that Graham did not apply this term as loosely as is popular at the present time. In his remarks on the properties of colloidal tungstic acid[8] he says: "It is remarkable that the purified acid is not pectized by acids or salts even at the boiling temperature. Evaporated to dryness, it forms vitreous scales, like gum or gelatine." Note that he describes the dry residue as "scales, like gum or gelatine" and not as gel.

It is evident, then, that the original meaning of the term gel has not been adhered to and in fact is more often applied to the state best described as jellies. Shall we adhere to Graham's definition or shall we discard it, restricting the term gel and its modifications to jellies, as popularity favors, and do away with any special terms to describe coagula from sols by electrolytes, or residues formed by evaporation to dryness? Special terms to describe these last two cases are obviously unnecessary and serve only to encumber colloid chemistry.

Use of "Peptization."

Lately the word "peptization" or "peptinization," as originated by Graham, has shown tendencies of wider use than formerly. Graham used this expression to describe the formation of a sol from a gel by the influence of a small amount of foreign reagent as, for example, the formation of a hydrous ferric oxide sol from a coagulum of ferric hydroxide by treatment with a small amount of hydrochloric acid or ferric chloride. He named it "peptization" because it resembled the hydrolysis of egg white to peptone by acid.

Cassuto, Hatschek, von Weimarn and Zsigmondy preserve the original sense of this term. Bancroft[9] has recently proposed, however, that we use peptization to describe all cases of transformation of gel (using this term in the present popular sense) to sol and not restrict it merely to cases where a foreign electrolyte has been added to accomplish the change; *e.g.*, when dry gelatine is "dissolved" in water Bancroft would call it a case of gelatine being peptized by water. This usage has its merits because it eliminates the word "dissolve" and the implication of "solution."

Ostwald defines peptization as the phenomenon opposed to coagulation.

Taylor prefers a new term, "solation," which he applies to all cases of gel ➔ sol transformations, and incidentally he urges the adoption of "gelation" to define all cases of sol ➔ gel transformations instead of coagulation or pectization.

"Pectization," another of Graham's terms, is rapidly dying out. The word "coagulation" covers all cases of pectization and therefore why preserve an unnecessary term? Furthermore, why adopt the new term "gelation" proposed by Taylor. "Coagulation" is adequate. Of course, if it is decided to name jellies (stiffened sols) "gels," then the word "gelation" would be a good one to describe the "setting" of the gel or the stiffening of the sol.

Elimination of Synonymous Terms.

Elimination of some synonymous terms is decidedly necessary from the list of names applied to the two more or less distinct classes or systems of colloid dispersions. For example, these two systems are variously named as follows:

Autbors		
Noyes[10]	Colloidal solutions	Colloidal suspension
Hardy,[11] Zsigmondy[12]	Reversible colloids	Irreversible colloids
Billitzer[13]	Baser collodis	Typical or genuine colloids
?	Hydrophilous colloids	Anhydrophilous colloids
Henri[14]	Stable colloids	Unstable colloids
Perrin, Freundlich,[15] Neumann[16]	Lyophilic colloids	Lyophobic colloida
Eary[17]	Dissolving colloids	Electrical colloids
Wo. Ostwald[18]	Emulsion colloids	Suspension colloids
von Weimarn[10]	Emulsoids	Suspensoids
Burton[20]	Gelatinizing type	Non-gelatinizing type

The terms "emulsoid" and "suspensoid" are very popular. "Lyophilic" and "lyophobic" are very expressive. The "stable-unstable" and the "reversible-irreversible" terms should be abolished, since they describe the conduct and changes in state of colloids when subjected to external conditions and are not always sharply defined. For example, hydrous ferric oxide sol is fairly stable in the presence of neutral electrolyte (much more so than colloidal gold or platinum), while it is irreversible when evaporated to *dryness*. Most writers classify it with the suspensoids, although Taylor calls it an emulsoid (since if it be evaporated *not quite* to dryness it is partially reversible). In reality it belongs to neither of these two generally accepted classes; its properties place it midway between the two, nearer the suspensoid than the emulsoid class. All the hydrous oxides of the basic or acidic elements act similar to hydrous ferric oxide.

On account of this confusion of classification Bancroft[21] has suggested that the distinction between these two groups be done away with. He prefers to classify colloidal systems according as to whether water or the more mobile phase is the internal or the external phase and states: "While we are reasonably sure that colloidal gold is a solid and that colloidal oil is a liquid, the two behave exactly alike when both are suspended electrically."

This suggestion is along the proper lines, but is too sweeping, since colloidal gold and colloidal oil do not behave alike.

After a consideration of all the terms, it would seem that "lyophilic" and "lyophobic," or their more special derivatives, "hydrophobic" are the least objectionable terms, since most colloids answer to one of these designations. When our knowledge of colloids becomes exact enough to *sharply* differentiate between these two classes then we may find names for those systems which now seem to have properties which place them in neither of the above.

Before concluding, attention is directed to the irritating, although not very serious, mistake in the translations of the German terms "disperse" and "dispersions Mittel" by some authors. The German adjective "disperse" is "dispersed" in English, not "disperse," and "disperse Phase" is dispersed phase," while "dispersions Mittel" is "dispersion medium" and not "dispersion means." These mistakes are like the old one of translating "Wanderung der Ionen" "wandering of the ions" instead of "migration of ions."

New Sources of Fertilizing Elements

(*Continued from page 335*)

amounts to about three pounds per barrel of cement, or to about 60 per cent. of the total potash that enters the kilns. This is now separated by leaching from the rest of the dust with which it is collected, and is placed on the market in the form of a concentrated salt containing about 80 per cent. of potassium sulphate. At other plants, as the Security Cement & Lime Company, the potash is not separated from the dust, but the mixture of both is disposed of directly as collected for use in the manufacture of fertilizers.

In an investigation recently completed in the Bureau of Soils, it was shown that the potash that escapes from the different cement plants of the country varies from 0.35 to 5.34 pounds per barrel of cement, with an average of about 1.9 pounds. Taking 90,000,000 barrels as the average annual production of cement in this country, then it may be estimated that the total potash escaping from all the cement plants of the country as at present operated amounts to about 86,000 tons annually. Assuming, in the light of results already obtained, that it would be possible to recover in available form, say, 80 per cent. of the total escaping, then the available potash that would be possible of recovery in the cement industry of this country amounts to about 75,000 tons annually.

It has been shown, moreover, that the amount of potash that escapes from cement plants may be increased by increasing the percentage occurring in the raw material or by increasing by chemical or other means the percentage of potash volatilized. If the same relative increase in the potash volatilized could be effected in all plants as has already been secured in some plants where potash is now being recovered, then the available recoverable potash in the cement plants of the country would be increased from 70,000 tons to about 100,000 tons annually. Still greater possibilities are to be expected by the use of feldspar and other potash minerals in the raw materials, and it is for reasons such as these outlined that the cement industry is looked upon as one of the principal potential sources of potash supply in this country.

Part VI.

Zinc, 65.37.

Zinc melts at 419° C. and boils at 918° C. It has a valency of two.

An alloy of zinc and copper was known to the ancients, who believed it to be a peculiar form of copper. It was not until the year 4 B. C. that Aristotle discovered that this metal could be prepared from copper and a peculiar earth found on the shores of the Black Sea. To this product Dioscorides and Pliny gave the name "Cadmia."

In the writings of Paracelsus (1520) we find zinc spoken of as a metal and it is to him we give the credit of its discovery as such.

Zinc Chloride, 136.29
- *Zinci Chloridum*
- *Butter of Zinc*
- *Muriate of Zinc*

Zinc Oxide, 81.37
- *Zinci Oxidum*
- *Flowers of Zinc*
- *Nil Alba*
- *Nil Album*
- *Oxide of Zinc*
- *Zinc Powder*
- *Zinc White*

Zinc Sulfate, 354.80
- *Zinci Sulfas*
- *Salt of Vitriol*
- *White Copperas*
- *White Vitriol*

Miscellaneous Synonyms.

Aerugo—*Basic Carbonate of Copper.*

[THE END.]

Fertilizing Elements

(*Concluded from page* 340)

Since fertilizers are food for plants it will follow that plants, and particularly certain parts of plants, may serve as fertilizers for a new crop. At one time a plant waste known as cottonseed meal, obtained in the manufacture of cottonseed oil, constituted the largest single source of nitrogenous material used in fertilizers, and the quantity still used for this purpose is in excess of 300,000 tons annually. A case of this kind is seen in the recovery of potash as a by-product in the manufacture of nicotine from tobacco waste. This is another illustration of the use as a fertilizer of a waste product recovered in the utilization of a waste.

Summing up, it may be stated that industrial wastes furnished about 40 per cent. of the potash, 8 per cent. of the phosphoric acid, and 85 per cent. of the nitrogen used in this country in 1916.

The potash was obtained from such wastes as tobacco stems, cottonseed hulls, hardwood ashes, wool washings, blast-furnace flue dust, cement flue dust, and sugar residues; the phosphoric acid was furnished by such materials as bones, shells, fish scrap, and basic slag; and the nitrogen was obtained from wastes in the manufacture of castor, linseed and fish oils; from animal wastes, as blood, hair, horns, hoofs and hides; from leather and wool wastes; from coke; and from a long list of other substances.

GAS

Why Be Without It?

It will doubtless be of interest to chemists and many of our readers to know that The Detroit Heating & Lighting Co., Detroit, Michigan, are manufacturing what is called the Detroit "Combination" Gas Machine.

The gas machine automatically manufactures from gasoline—without the use of artificial heat—a gas which is used for every purpose where public coal gas is used and the cost is no greater. Among some of the many uses of this gasoline-gas is: operating bunsen burners in the laboratory, blast lamps, muffle furnaces, bunsen liquids and in the machine shop for annealing, tempering, soldering and other uses.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS[*]

Part XVI

As installed in the laboratory the lamp case described in the preceding installment of this article is provided with a flue which passes up into the ventilator of the chemical hood. This flue is not necessary when the lamp is used in connection with the beaker described above. When used without the beaker, however, the ozone produced makes the laboratory a very unpleasant place in which to work, unless some means are provided for carrying the exposed air out of the room. The flue also disposes of a great deal of heat.

It is difficult to give an accurate description of the intensity of the light produced. Judging from the current density the light is much more intense than that produced by any lamp which has been previously described. Perhaps the following statement will serve to give an idea of the efficiency of the lamp in producing ultra violet rays: It is known that egg-white is slowly coagulated by ultra violet rays. Bovie states that in order to test the lamp, egg-white was diluted with water to make a 2% solution. The solution was brought to its isoelectric point and filtered clear; 100 cc. of the filtrate were placed in the beaker of the lamp, and the stream of water passing through the water-jacket was adjusted so that the solution of egg-white had a temperature of 16°. A flocculent coagulum began to appear 4 min. after the lamp was lighted. In this experiment the lamp was carrying a current of 11 amperes. (The amount of light probably varies as the square of the current density.)

Data on the expansion of fused quartz are given by *Henning* (Ann. Physik. 1903, (iv), 10, 446; J. Chem. Soc. 1903, Abs., *84*, ii, Page 272) for temperatures up to 1000°. It is found that the mean increase of unit length for a rise of 1° is 0.00000054.

Patent Leather.

An apparatus for the treatment of patent leather with ultra violet light is recommended by *Priest* (U. S. Patent 1,262,977, April 16, 1918, J. S. C. I., 1918, 343A), who states that after leather is coated with the linseed oil varnish mixture customarily employed, the stock is exposed to the direct rays of the sun for a period of 8 or 10 hours. The drying takes place best in clear, cool weather, and is greatly retarded by a humid atmosphere. In order to dry the leather rapidly, Priest uses ultra violet light, which accomplishes the drying operation in from 2 to 6 hours. An apparatus employed by Priest is shown in *Fig. 1*. A frame arranged on bearings so that it may be revolved serves as a support for the hides which are to have their varnished surfaces exposed to the direct action of the ultra violet rays. A series of quartz burners are arranged vertically in the center of the revolving frame. The frame is placed in a drying room having heating coils and heated air may also be introduced through a pipe entering the revolving frame at the bottom. The action of the ultra violet rays may also be supplemented, according to Priest, by the use of ozone.

Ozone Apparatus.

The production of ozone by ultra violet light, as practised by *Potter* (U. S. Patent No. 854,965, May 28, 1907) involves the use of a form of apparatus shown in *Fig 2*. A mercury silica lamp is inclosed by a double walled jacket. A current of air is passed through the inner annular space next to the lamp, while water is supplied to the outer space for cooling purposes. The inner wall of the jacket may be of silver, glass or other reflecting material which will serve to protect the operator from any ill effects of the rays.

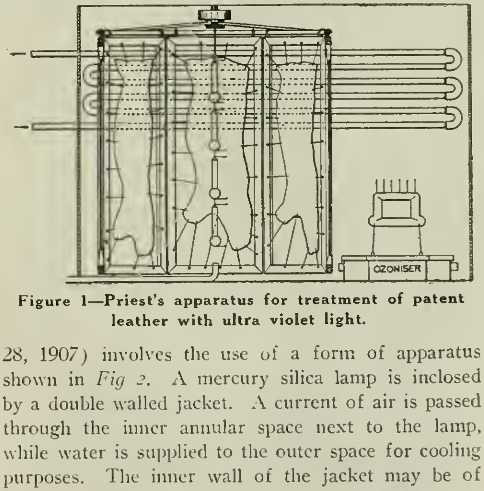

Figure 1—Priest's apparatus for treatment of patent leather with ultra violet light.

Chloroform and Other Chlorides of Methane.

Bedford (J. Ind. Eng Chem., 1916, *8*, 1090) has made some interesting observations on the chlorination of methane, which while strictly speaking do not involve the use of ultra violet light, nevertheless are indicative of methods which may be advantageously employed in carrying out some reactions through the agency of ultra violet light. He observes that one volume of chlorine in seven volumes of natural gas will react quickly in the presence of light from the "White Flame Arc" (Mott and Bedford, J. Ind. Eng. Chem., 1916, *8*, 1029), but without explosion. If reactions with fresh quantities of chlorine be repeated, the speed of the reaction finally slows down as the residual gas becomes diluted with chlorine, hydrogen chloride, nitrogen, air, etc., until finally no more reaction will take place without the aid of external heat.

---

[*] All rights of publication in book form reserved by the authors. Consulting Chemists and Chemical Engineers, 92-98 Greenwood Ave., Montclair, N. J.

The effect of concentration of free chlorine on the chlorination of methane was studied in the following manner: Natural gas was confined in a bell jar over water at about 20°C. and chlorine was added by bubbling it in through the water. A uniform mixture of the gases was obtained by shaking the jar and splashing the water. The access of diffused daylight, during the short period, produced little or no reaction as long as the percentage of chlorine in the gases was low. Upon suddenly exposing to the light from the "White Flame Arc" there was an instantaneous expansion of the gases, even when the chlorine content was small. After the reaction, the water was shaken up through the gases, thereby cooling them, removing the hydrogen chloride and condensing such reaction products as were liquids at the temperature of the water.

Fig. 3 shows the results reported by Bedford on chlorinating natural gas, while the latter was confined over water at room temperature, the chlorine being added in increments of either 500, 250, or 125 cc. After mixing the gases, they were exposed to the light and then cooled by shaking up with the water. After each cycle of operations, the volume of the residual gas was noted and its contraction from the original gas volume calculated. Before the experiments were started, the water was saturated with chlorine and with natural gas; the slight increase in temperature of the water, during the reaction was found to aid rather than hinder the process. Starting with three liters of natural gas, there was always an unreactive residue of about 200 cc., showing that about 2,800 cc. would react with the chlorine under these conditions.

The horizontal dotted lines in *Fig. 3* represent percentages of the total contraction obtained and aid in the study of the curves. The vertical dotted lines represent volumes of chlorine equal to and twice the total contraction in gas volume.

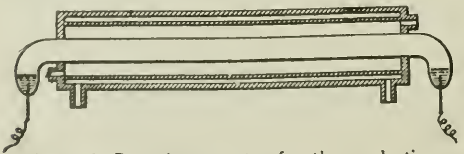

Figure 2—Potter's apparatus for the production of ozone.

Ice As a Cooling Agent.

The attempt to obtain better cooling in order to prevent entirely the formation of tetrachloride, finally led to the carrying out of the reaction in the interstices between cakes of ice. It was predicted by Bedford that by filling the reaction chamber with cracked ice, he should obtain only the di- and tri-substitution products, since methyl chloride is a gas at the temperature of ice and the others should condense out before forming the tetrachloride.

The first experiment in the chlorination of methane in the spaces between cracked ice presented the difficulty of improper gas circulation. The gases directly exposed to the light would react at once but further action took place only as the chlorine slowly diffused toward the light. The content of chlorine was increased until with a mixture of 4 vols. chlorine: 1 vol. methane, an explosion resulted, even in the presence of ice cakes the size of hen's eggs or smaller. After Bedford had made many variations in the apparatus, the one shown in *Fig. 4* solved the difficulty.

An 8-liter, two-neck Woulfe flask, with the bottom removed, was placed over a single ice cake chipped to nearly fill the flask. As the ice melted in the top of the reaction chamber, the flask settled upon it keeping ice in the top of the chamber where the cooling is most needed, until the bottom of the flask touched the bottom of the vat, whereupon the ice melted away from the top of the flask and allowed gradual increase in the volume as well as in the temperature of the gas above, until carbonization took place. The dotted lines show the points of highest temperature as shown by the melting of the ice. Upon starting the reaction, by means of the White Flame Arc light, with the chlorine content of the gases about 1 in 8, the circulation was found to be rapid and violent. The gases passed upward on the side next to the light, drawing the cold gases from around the ice cake below. It was found that 2.6 cu. ft. of natural gas gave 166 cc. of reaction product which is equivalent to about 17 gal. per 1,000 cu. ft. This included the methylene chloride and chloroform dissolved in the water, which were separated by distillation.

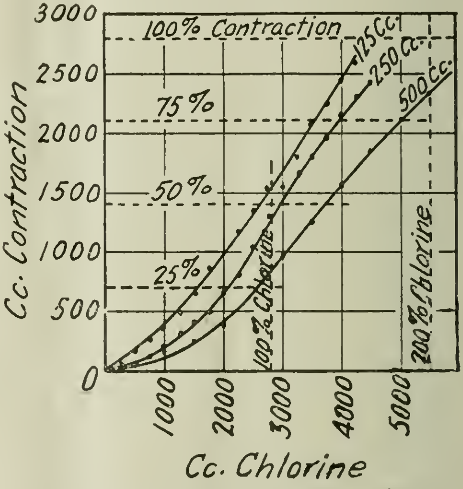

Figure 3—Graph showing Bedford's results on chlorination of natural gas.

The apparatus shown in *Fig. 5* was designed to prevent the access of light to the large volume of gas left in the top of the reaction chamber by the melting of the ice and also to furnish a larger supply of ice per charge. A 10 in. sewer pipe "tee," with the side outlet near the bell end, was supported on three bricks and set in a vat of water. The side outlet was closed with a circular piece of plate glass sealed in with litharge-glycerine cement. The tile was filled with pieces of ice the size of coconuts or larger and the top closed with a wooden lid made gas-tight by rubber coverings. After removing the air by suction through an opening in the lid, natural gas and chlorine were admitted at the same relative points as in *Fig. 4*. The capacity of the tile was found to be about $3\frac{1}{4}$ cu. ft. of gas per hr. and a total of 18.5 cu. ft. gave 1.1 liters of product having the following composition by volume (percentages).

Methylene Chloride	Chloroform	Carbon Tetrachloride	Ethane Products
35.5	47.5	4.0	13.0

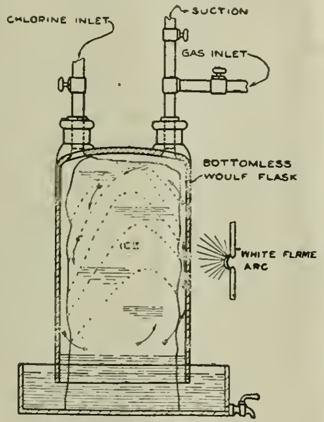

Figure 4—Bedford's apparatus for the chlorination of methane.

Fig. 6 shows a large wooden reaction chamber, 28 in. by 28 in. by 44 in. inside dimensions, built for the carrying out of the reaction on a larger scale, and practically duplicating that of *Fig. 5*. In one experiment using 250 cu. ft. of natural gas, the rate of consumption varied from 14 to 30 cu. ft. per hr. and several gallons of product resulted. The analysis of the liquid reaction product separating out under water was as follows, percentages being by volume:

Methylene Chloride	Chloroform	Carbon Tetrachloride	Ethane Chlorides
35	35	5	20

The analysis of the part soluble in the water and separated by distillation was:

Methylene Chloride	Chloroform	Carbon Tetrachloride	Ethane Chlorides
61	28	1.5	6

About 14 per cent. of the reaction product dissolves in the water produced from the melting of ice by the heat of the reaction. This soluble portion may be entirely recovered by distilling off 5 per cent. to 10 per cent. of the water, the methane chlorides coming over with the distillate, and the residue being about a 5 per cent. solution of hydrochloric acid provided no water has been added except that produced by the melting of ice. About 135 lbs. of ice are necessary for the production of one gallon of product having the composition as given above and the HCl from the reaction is thereby greatly diluted.

In the chlorination of pentane, *Brooks, Smith* and *Essex* (J. Ind. Eng. Chem. 1918, 511) found that once the chlorinating action had started it would proceed very smoothly in diffused daylight, and that ultra violet light was not necessary to effectuate the reaction.

Molecular Rearrangement.

Bodforss (Ber., 1918, *51*, 214) found that Benzoylphenylethylene oxide, benzoyl-m-nitrophenylethylene oxide, and benzoyl-p-chlorophenylethylene oxide undergo rearrangement into phenyl a-hydroxystyryl ketones with increasing readiness when their methyl-alcoholic solutions are exposed to the light of a mercury lamp. The yields of the isomerides are very small, but their presence can be demonstrated by the ferric chloride test for enols and by the precipitation of copper salts, from which they can eventually be isolated.

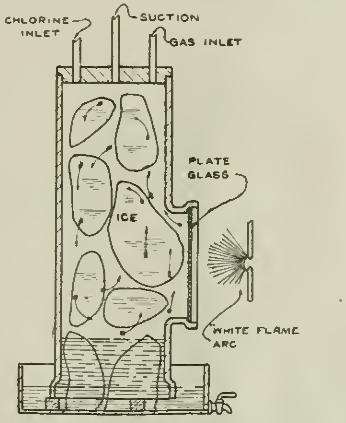

Figure 5—Modification of Bedford's apparatus, designed to eliminate light.

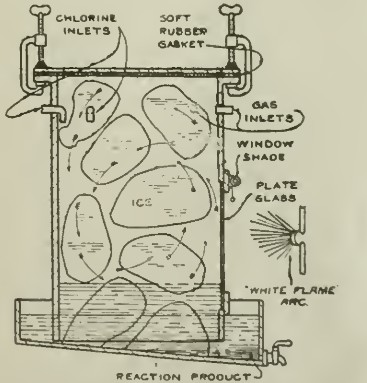

Figure 6—Bedford's design for large scale chlorination of methane.

Lamp for Bacteriological Purposes.

A form of quartz tube mercury lamp recommended by *Knipp* (Phys. Rev., *30*, May, 1910, 641) for bacteriological work is shown in *Fig. 7*, which illustrates the tube and manner of mounting. The diameter of the main branch AB is 25 mm., and the length of the straight portion 15 cm. It had, as used in *Fig. 7*, three outlets. The tubes AM_1 and BM_2 are 20 cm. long and 4 mm. internal diameter, while the exhaust nipple *mn* was somewhat smaller in diameter. The tube was hung on two asbestos-covered pegs mounted on a suitable support. Glass extensions M_1E_1 and M_2E_2 were added of sufficient lengths to support the barometric columns AE_1 and BE_2 respectively. Mercury seals insured tight joints at M_1 and M_2. The vessels E_1 and E_2 served also as the leading-in terminals to the arc. After exhausting the tube it was sealed off beyond M_3. The arc was started in the usual way—by lifting E_2 slightly until the mercury would flow from B down to A. The mercury levels at A and B were adjusted readily by raising or lowering E_1 and E_2.

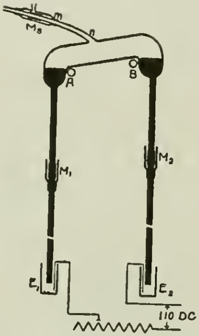

Figure 7—Lamp recommended by Knipp for bacteriological work.

This arc was suited only for low voltages and hence gave out comparatively weak ultra violet radiations. Any attempt to increase the energy consumption would, because of the vapor pressure, depress the mercury electrodes at A and B. In order to obtain a more intense light the shallow vessels E_1 and E_2 were replaced by narrow tubes (about 1.2 cm. in diameter) extending some distance up the barometric legs. This method automatically kept the mercury surfaces at A and B at practically constant levels, and admitted of a small range of light intensity. However, another difficulty was encountered; the increased temperature of the arc interfered with the seal at M_3. In the attempt to obtain a light source of much greater intensity the manner of setting up the tube was changed as follows:

The exhaust nipple *mn* in *Fig. 7* was fused off near the main tube, and instead connection was made below the mercury seal M_1 as shown in *Fig. 8*. This exhaust tube should join the barometric leg at a point *p* far enough down to admit of lowering the seal M_1 A valve protected by a mercury seal is placed at V_3. The lower end of the leg is shaped in the form of an S having a valve V_1 in its outer right-hand limb and a No. 24 Pt. terminal wire sealed into a projection from its middle limb. In the figure, the terminal E_1 is shown in the plane of the paper, while in actual construction it is more conveniently joined to the front. This allows the S to be made more compactly than shown. The opening t_1 to the projection carrying the terminal E_1 should be rather large, otherwise some difficulty may be experienced in filling it with mercury. The length of the leg M_1E_1 must be such as to support a barometric column below the point *p* and thus not interfere with the process of exhaustion.

The leg M_2E_2 as will be seen by the figure is similar to the other with the following exceptions: The point *q* is 760 mm. below the mercury level at B. At *q* is joined a manometer tube about 150 cm. long and 3 mm. internal bore with its upper end *r* open. A mercury reservoir N is joined by a short rubber tube to the outlet below the valve V_1 as shown in the figure.

To operate: Fill the cups shown at the terminals E_1 and E_2 with mercury and connect the same through a suitable resistance R and switch S to a 110-volt, or in case very intense light is desired, 220-volt D.C. source. Include an ammeter and voltmeter in the circuit. Now close the valve V_1 and open the Valves V_2 and V_3. Let the outlet below V_1 dip into a vessel F containing mercury. Pour mercury into the reservoir N until the mercury rises above the valve V_2 and then close it. Close *r* with a rubber tube and pinch-cock, and then start the pump. After a few strokes close V_3 and open the Valves V_1 and V_2 slightly. This serves to fill the projections at E_1 and E_2. Repeat the operation if necessary. Now open V_1 and V_2, pour a considerable quantity of mercury into N, open the pinch-cock at *r*, start the pump and then open the valve V_3. After continued pumping the mercury should stand below *p* in the leg AE_1 and at B in the leg BE_2. When the tube AB, upon sparking, is found evacuated sufficiently (and it is well to let the apparatus stand over night before sealing off) close V_1 and pour mercury slowly into N. The mercury will over-

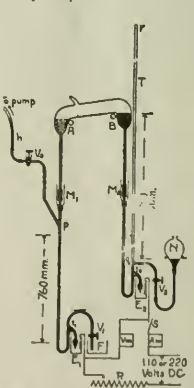

Figure 8—Adaptation of Fig. 7 to production of more intense light.

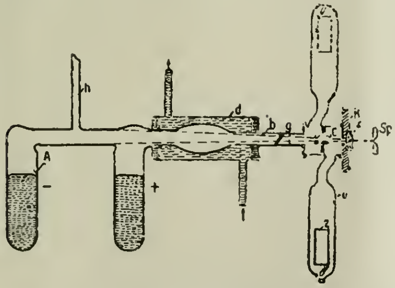
flow at B and fill the leg AE_1 rising in both branches and "seal off" the system from the pump. When the mercury has reached *h* in the exhaust tube close V_3, and when it has reached A in the main tube close V_2. The quartz tube is now ready to start the arc. Close the switch S and open the valve V_2 only long enough to let a stream of mercury flow from B to A. If properly exhausted the tube should light up at once. As the arc burns the current falls off in value. By keeping the current constant—increasing the impressed voltage—the arc will exhibit the characteristics as described by Küch and Retschinsky (Ann. d. Phys. 1906, *20,* 563) for increasing vapor pressures. The pressure is read by the manometer *qr* and may exceed with safety one atmosphere.

The quartz tube AB may have almost any shape which the needs of the investigation may require, keeping in mind the manner of starting the arc. The electrode B should be comparatively large in area so that a slight depression of the mercury will correspond to a considerable height in the manometer tube *qr*. Either A or B may be the anode. As A fills up, by condensation and also by overflow from B, it may be lowered at will by opening V_1 for a moment. In case the vacuum falls the tube can be exhausted readily again. The valves should be worked dry to avoid contaminating the mercury. To give added strength to the joints at M_1 and M_2, the pure gum tubing used should be wound over with one layer of adhesive tape which in turn should be wrapped with strong thread. The conduction of heat from the electrodes to these joints is not sufficient to injure them even for continued running at high pressures.

Some of the advantages of this form of quartz tube mercury lamp are: Simplicity of the quartz tube; ease of starting the arc and adjustability of the mercury surfaces at A and B; apparatus may be taken apart readily for purposes of cleaning or for introducing different materials into the arc; when properly mounted it is quite portable.

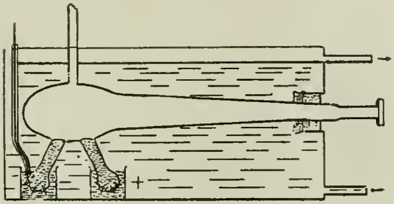


(Photostat copy from N. Y. Public Library.)

Figure 9—Apparatus used by Wolff for study of extreme ultra violet.

Apparatus for Extreme Ultra Violet.

For the purpose of making investigations in the extreme ultra violet *Wolff* (Ann. Physik; 1913 (iv) 42. 825) used a quartz lamp of the Stark and Küch type (Phys. Zeitsch. 1905, *6,* 438) made by Heraeus. (*Fig.* 9) shows the construction of the apparatus. The lamp A has a water-cooled side tube b which is connected with a Geissler tube shown on the right. The latter is closed by a perforated plate K, over which is fastened a fluorite plate f. The tube h of the lamp A is connected to a pump. In order to control the time of exposure and to avoid the presence of metal vapors in the Geissler tube and on the fluorite window, a valve of sheet iron g is arranged in the tube b in such a manner as to be actuated by an electromagnate placed outside the tube.



(Photostst copy from N. Y. Public Library.)

Figure 10.—Another form of lamp used by Wolff.

A modified form of lamp used by Wolff is shown in *Fig. 10*. An elongated bulb of glass is set in a water bath. The bulb has two tubes in the lower side for mercury. An exhaust tube is situated at the top. At the right hand end is placed the fluorite window. The mercury vapor condenses on the walls of the bulb so effectively that the window does not become coated with mercury even after operating for a considerable period. These lamps are started by an induction coil and are operated at 220 volts.

Beet Sugar Pulp as Cattle Feed

An idea of what is being done by large industrial enterprises in utilizing waste materials is furnished by the annual report of the American Beet Sugar Company. This concern several years ago began converting the pulp which it had previously thrown away into a valuable food for cattle. While for the year ending March 31, 1917, the return from the pulp amounted to $198,022, the net receipts for the succeeding year totaled $314,324, and was more than sufficient to pay the dividend on the preferred stock of the company.

"At Oxnard, Cal," says the report, "after experiments during the last three campaigns, a plant is being erected at an estimated cost of $123,939 to extract from the water which is now run into the ocean, potash, ammonia, etc., the market value of which has advanced so rapidly during the war. This plant, it is expected, will be ready for operation when the factory begins work the coming summer, and it is estimated that the profit on its production this year will exceed its cost, and that hereafter, even with peace prevailing, the value of its product will insure continued profitable operation."

Plans for Chemical Show

(*Continued from page 333*)

tions and needs. Dr. Charles H. Herty and Dr. G. W. Thompson, president of the American Institute of Chemical Engineers, are to make opening addresses. F. J. Tone, president of the American Electrochemical Society; Dr. W. H. Nichols, president of the American Chemical Society, and several others are expected to make addresses also. Joseph W. Richards will speak on "Ferro Alloys of silicon tungsten, uranium, vanadium, molybdenum and titanium." Richards is a member of the Naval Consulting Board. Theodore Swann, president of the Southern Manganese Corporation, will speak on "Ferro Manganese."

The program for the exposition is in active preparation. There will be a series of symposiums on the "Development of Chemical Industries in the United States, notably since July, 1914." This will embrace the period since the beginning of the European war, which because of its removing the source of supply for our domestic industries inspired the development of our own chemical industries that, now, when we ourselves have entered the war, are proving so efficient. This program is divided into a consideration of Potash Development, on which Mr. C. A. Higgins, of Hercules Powder Company, will speak of the operations of that company in its recovery from kelp; Mr. Linn Bradley, of Research Corporation, of its recovery from cement dust and other sources by electrical precipitation.

There are to be other symposiums on chemical engineering, acids, industrial organic chemistry, the cheramic industries, and the metal industries, and among the speakers are:

A. Hough—"Chemical Engineering in Explosives, T N T; T N A; Picric Acid and Nitrobenzol."

E. J. Pranke—"Development of Nitric Acid Manufacture."

S. P. Sadtler—"Development of Industrial Organic Chemistry."

Geo. H. Tomlinson—"Wood as a Source of Ethyl Alcohol."

C. A. Higgins—"Kelp as a Source of Organic Solvents."

Alcan Hirsch—"Pyrophoric Alloys."

The American Ceramic Society, which will hold its meeting at the exposition on Thursday afternoon, September 26, has already upon its program the following:

A. V. Bleininger—"Recent Developments in the Ceramic Industries."

L. F. Barringer—"Manufacture of Electrical Porcelain" (illustrated by motion pictures).

H. Ries—"American Clays."

F. A. Whitaker—"Manufacture of Stoneware" (illuminated).

Following this meeting a series of motion pictures of the ceramic industries will be shown. The motion picture program with the arrangement of which the Bureau of Commercial Economics is again co-operating, carries forward the idea of the symposiums, and pictures will be shown of industries that have developed, in so far as they can be shown with propriety.

There will be shown a series of motion pictures depicting studies of lakes, water falls, and hydroelectric power possibilities. The development of some of these will be carried through the several stages of construction, generation and transmission of the power and its use in industrial operations. Films of several electro-chemical operations will be shown.

There will be pictures of many chemical, mining and related industries, the application of electricity and electrical equipment to industrial work. There will be pictures showing the alkali industries that will be shown the same day on which the potash symposium is held. The making of glass, pottery and stoneware pictures will be shown on Thursday, September 26. Pictures of the oil industries, petroleum, asphalt, fatty oils, soaps, paints, linoleum and oil cloth will be shown. In fact, every field of endeavor from the products within, upon and above the earth with which chemistry deals will be shown. There will be a series of films depicting carelessness, the destruction of life, wealth and resources that show hazards and risks in industrial plants and how they may be overcome. The dangers of fire and explosives will be demonstrated and the prevention of disease of vaccines.

The list of exhibitors of the exposition is a very complete one of the best firms among or supplying the chemical industries, firms who are placing their faith in the future of America and the men who are building to successfully conclude this war and to meet world trade competition after. Many of the exhibitors are supplying motion pictures that will be shown on the program. More complete details of the program, motion pictures and exhibits will be given in our next issue.

While the exposition will bring manufacturers of machinery, equipment, products and supplies together with men who are using them, its chief effect will be to show the people of the country that the chemists of America have made rapid advances in the past year, greater than ever before in this country's history. Much of the success of winning the present war depends upon chemicals and the chemical engineer. The convention will bring to light some of the marvelous results of recent research, and many engineers and experts who hold important positions in the advance of the chemical industry will be speakers at the various industrial conferences. The proceedings will develop matters of timely interest to the public as

Crudes, Intermediates. Artificial and Natural Colors. Synthetic Medicinals, Flavors and Perfumes. Explosives, Photographic Developers.

National Aniline Continues Education of the Consumer

The National Aniline & Chemical Company, Inc., has always extended the facilities of its laboratories and the service of its technical men to the textile and other trades. Such service as this has become an important department in the National organization.

The war with its resultant difficulties has added another problem. In all great crises numerous concerns spring up which are inadequately prepared to handle a business as technical as that of dyestuffs. Goods get upon the market which are not suitable; the textile manufacturer is misled; goods imperfectly dyed or which have been dyed with the wrong color come upon the market; and the public, uninformed as to conditions, finds difficulty in judging between what is good and what is bad. This is particularly harmful to an industry as much needed by America as that of dyestuffs. It therefore has become important that distributors of the finished garment should be informed as to the present color situation.

With this in view the National Aniline & Chemical Company, Inc., is extending to clothiers, department stores, and others, the facilities of its laboratories for the examination and report on any fabric in which they may be interested. The reasons prompting this invitation are fully set forth in the following letter which has been sent to a large number of such merchants:

"In the emergency existing for a few months after the outbreak of the war—the transition period before the establishment in this country of the present great artificial industry—many kinds of worthless dyes were used—in some cases long after it was necessary, and the retailer and distributor of dyed garments commenced a campaign of explanation to the consumer to remove from their shoulders the responsibility of badly dyed fabrics. This explanation was based upon the assumption that in the absence of German dyes good work could not be secured. The explanation became a habit.

"To make such a statement today is untrue, and if continued after an opportunity has been given to investigate might be interpreted as German propaganda. This company and its predecessors have for years invited the mills to submit their problems in dyeing, and the necessary scientific tests and reports have been made without involving the recipients in any obligation. It is proposed now to extend this facility to the garment manufacturers, to the retail dealers and to the department stores.

"To this end we are prepared to make tests of any of your fabrics and to report to you the quality of the dyestuff used; its comparative merits with the dyestuffs used prior to the war; its fastness to light, to washing, and any other requirements which you may be interested in. This will be done without charge, and in accepting such service no obligation is incurred. Our sole object is to demonstrate the comparative merits of American and foreign dyes.

"For your information we hand you two publications of ours which will suggest to you the broad and stable basis upon which this American industry is now building."

Alizarine Red Now Made in America.

In January of this year, the National Aniline & Chemical Company, Inc., made this statement in its house organ, "Dyestuffs": "The interesting things hoped for in 1918 are the placing on the market of alizarine red, or indigo, and of hydron blue. The consuming trade looks forward with expectancy to these accomplishments. Other things are hoped for, but these are promised." The development of synthetic indigo at Marcus Hook was announced some months ago. At the recent textile show in Grand Central Palace the National Company displayed two large globes, one filled with indigo and the other with alizarine. It now announces that alizarine is actually being placed in the hands of the consumers, the first shipments having already gone out.

Up until the beginning of the war the big alizarine industry was almost entirely German. It was in 1868 that two German chemists, Graebe and Lieberman, determined the constitution of the product and succeeded in manufacturing not only alizarine but also purpurine. Upon this investigation also depended a number of subsidiary processes of great importance: the manufacturing of bichromates and fuming sulphuric acid. The discovery of alizarine practically eliminated the entire madder industry, which flourished especially in France, and many hundreds of thousands of acres which had formerly served for the cultivation of madder were now available for foodstuffs. Madder has almost completely disappeared from the markets because it could no longer compete with alizarine in purity, strength, and especially uniformity in quality. There are still some dye houses in Europe which from force of habit prefer madder to alizarine, but it is universally conceded that, especially for the calico printer, alizarine produces results which were not possible with madder.

Alizarine, so named by Robiquet and Colin after "Alizari," the commercial name of levantine madder root, is a derivative of anthracene, which is contained in coal tar. Anthracene is usually oxidized with sodium bichromate and sulphuric acid, and the resulting anthraquinone transformed into a sulphonic acid. The sulphonic acid is then melted with caustic soda and transformed into alizarine in closed vessels under pressure. The chemical name of alizarine is dioxyanthraquinone. It is a reddish yellow powder in its pure state, or appears in brilliant orange red needles at the melting point of 289-290°. It is practically insoluble in cold and very little soluble in boiling water. It dissolves completely with a reddish orange color in boiling alcohol, ether, and carbon disulphide, glycerine, glacial acetic acid, benzone, and turpentine. Cautic soda dissolves it with a bluish violet shade. Muriatic acid precipitates the dyestuff from this solution.

Dyeings produced from alizarine are distinguished by great brilliancy and excellent fastness to light and washing. When applied to cotton in connection with aluminum mordants, the so-called Turkey Red, the fastest red known to the art of dyeing, is produced. It is for this Turkey Red that alizarine has been needed most.

This alizarine of the National Aniline & Chemical Company, Inc., has been developed in the laboratory of its Brooklyn works, where it is now manufactured in a building erected for this purpose. This achievement with that of indigo does much to show the falsity in the position of those consumers who still doubt the ability of the American chemist and manufacturer to equal the product of the German, and to continue to supply the American consumer after the war. This American alizarine is of exactly the same quality in all respects as that formerly imported from Germany. It is now expected that the development of hydron blue, a fast blue for cotton, which is sure to follow, will meet the last objections of the remaining doubters.

National Sulphur Blue L.

This is the latest addition to the series of Sulphur Blue now being manufactured by the National Aniline & Chemical Company, Inc., and places in the hands of dyers a product possessing considerable brilliancy.

This new blue is applied to cotton in the usual manner. Dyeing proceeds uniformly at a temperature of 140° F. The dye bath is charged with a quantity of the dyestuff necessary for the desired shade, together with an equal weight of sodium sulphide concentrated, and also 3 to 5 per cent. of soad ash and 15 per cent. of common salt. Complete reduction of the dyestuff in the bath is noted when the color of the solution changes to a reddish-gray.

National Sulphur Blue L is advantageously aftertreated with metallic salts, which are applied in a separate bath. Those recommended, with this mode of application, are bichromate of soda and acetic acid which slightly reddens the shade. Sulphate of copper (bluestone) and acetic acid dulls the shade, while a combination of bichromate of soda, bluestone and acetic acid produces a shade which is an intermediate between those which are produced with the metallic salts used singly.

Fastness of the dyeings produced with this new type of blue is very good; to *light*, it is very satisfactory and will answer for nearly all requirements; to *ordinary washing*, the shades are excellent, but under the influence of hard washing, the shade loses slightly, although both cotton and wool remain unstained; to *cross-dyeing*, the shade does not lose in depth, but is made slightly duller, but white wool and cotton remain quite clear. The dyed shades are particularly fast to hard fulling.

On the whole, it is a most satisfactory dyestuff, and will be found to meet the requirements of cotton dyers who have been in need of a fast bright blue of this type.

Dyers interested will, upon request, be supplied with full working details, with product sample, and dyeings from any of the company's branches.

Manufacture of 2-Amino-Anthraquinone

The anthracene derivative, 2-amino-anthraquinone, is widely used in the synthesis of vat dyes, notably in the production of indanthrene and its derivatives.

An improved method for its preparation is announced by P. Dutoit, of Monthey, Switzerland, assignor to the Society of Chemical Industry in Basel. (Amer. Pat. 1,255,719, of Feb. 5, 1918.)

The process consists in heating 2-anthraquinonesulfonic acid with ammonia and with an aromatic nitrocompound as, for instance, a nitrophydrocarbon or one of its derivatives. Hereby is obtained, besides the 2-aminoanthraquinone, as valuable secondary product the aromatic aminocompound corresponding to the nitrocompound employed.

The invention is illustrated by the folowing examples:

Example I: In an autoclave are heated 500 gr. of sodium 2-anthraquinonesulfonate with 100 ccm. of water, 1500 ccm. of ammonia of 26 per cent. and 240 gr. of nitrobenzene, for 24 hours at 190° to 200° C. After cooling the content of the autoclave is distilled with steam and 2-aminoanthraquinone, remaining in the form of crystals, is separated by filtration, washed with water and dried. Thus are obtained 290 to 300 gr. of aminoanthraquinone corresponding to an output of 81 to 84 per cent of the theory. By adding common salt to the motherlye small quantities of unchanged sodium anthraquinonesulfonate can be separated therefrom. From the liquid distilled off by the treatment with steam can be obtained about 90 gr. unchanged nitrobenzene and about 90-100 gr. aniline corresponding to the quantity of nitrobenzene consumed.

Example II: For the 240 gr. of nitrobenzene employed in Example I are substituted 440 gr. of sodium nitrobenzenesulfonate. After cooling the content of the autoclave is filtered off and the aminoanthraquinone thus obtained in crystalline form is thoroughly washed with water and dried. From the filtered liquid can be separated, besides unchanged nitrobenzenesulfonic acid, the quantity of anilinesulfonic acid corresponding to the sodium nitrobenzenesulfonate consumed.

Instead of those indicated in the examples, other aromatic nitrocompounds, as for instance, nitrotoluene, dinitrobenzene, nitronaphthalene, dinitronaphthalenes or their sulfoderivatives, etc., can be employed.

Device for the Sulfonation of Aromatic Hydrocarbons

A practical method for the continuous sulfonation of aromatic hydrocarbons has been devised by Hans Bull, of Philadelphia, (Amer. Pat. 1,247,499, of Nov. 20. 1917).

Use is made of the principle of counter-current and the mechanical arrangement is not unlike that of a battery of Shanks' lixiviating vats.

A series of tanks or closed receptacles is mounted one above the other, so that use may be made of gravity. Pipes lead from the bottom of each receptacle to a point half-way up the side of the receptacle immediately beneath. Bent pipes connect the top of each receptacle with the lower portion of the receptacle immediately above.

Sulfuric acid, or oleum, enters at the tops of the series and descends to the bottom by way of the first set of pipes. A hydrocarbon, liquid or dissolved in a convenient solvent such as naphtha, enters at the bottom, and passes upward through the second set of tubes, as the result of its lighter specific gravity.

The purer hydrocarbon thus encounters the less concentrated sulfuric acid and the more strongly sulfonated hydrocarbon meets the more concentrated acid.

The upward current of hydrocarbon, carrying with it the newly formed sulfonic acid, bubbles continuously through the descending current of sulfuric acid, and intimate contact is effected. As a result weak acid is drawn off from the bottom of the lower receptacle while the excess of hydrocarbon, containing most of the sulfonic acid produced, issues from the upper part of the topmost receptacle and is conducted to the separating apparatus.

This device is well adapted for carrying out the method of sulfonation recently patented by Prof. L. M. Dennis, and described in the pages of this journal.

The Manufacture of Chlorobenzene

Chlorobenzene is produced by the action of chlorine on benzene in the presence of a catalyst. The catalyst seems necessary to bring about the substitution of the hydrogen by chlorine. Without its aid, if benzene is acted upon by chlorine, the latter is simply dissolved, giving a yellow solution. After some time, and especially under the action of sunlight, white crystals with a camphor-like odor separate out. These are hexachloride of benzene, $C_6H_6Cl_6$.

If, however, the reaction takes place in the presence of a compound of iodine, iron, molybdenum, or antimony, the result is quite different. The chlorine reacts on the benzene, replacing the hydrogen:—

$$C_6H_6+2Cl=C_6H_5Cl+HCl.$$

It may be noted that the bodies ordinarily employed as catalysts are generally susceptible of two degrees of chlorination, ICl and ICl_2, $FeCl_2$ and $FeCl_3$ for instance. This helps to explain why minute quantities of them only are necessary, as the catalyst serves simply as a carrier for the chlorine.

It is true, however, that other bodies such as aluminum chloride will serve. This is explainable by the fact that there is an intermediary formation of a metallo-organic body which has a greater reactivity than has benzene. Whatever catalyst is used, the action does not stop at the formation of the monochloride; a second molecule of chlorine acts on the monochlorobenzene and transforms it into dichlorobenzene:—

$$C_6H_5Cl+2Cl=C_6H_4Cl_2+HCl.$$

While there is only one monochlorobenzene, three dichlorobenzenes are known. During the chlorination there is a major production of the para derivative, along with a certain quantity of the ortho isomer.

Pushing further the action of the chlorine, the trichloride of benzene is obtained, and notably the asymetric derivative 1:2:4, fusible at 17° C., and boiling at 213° C. Finally, if the action is sufficiently prolonged and energetic, the six atoms of hydrogen are replaced by chlorine and hexachloro-benzene $C_6H_6Cl_6$, which is the ultimate product of the substitution by chlorination, is formed. This is also known as Julin's chloride. The crystals melt at 226° C., and boil at 326° C.

These polychlorides are of no particular technical interest. The monochloride is a largely used product, and its industrial proparation is of constantly growing importance.

By the mononitration of chlorobenzene a mixture is obtained of the ortho and derivatives. They are separated by fractional distillation in a vacuum, followed by fractional crystallisation.

Orthonitrochlorobenzene is the raw material for orthonitro-anisol, from which dianisidine and anisiparatively simple. A standard type is that invented by Marckwald and patented in 1902.

The fundamental idea is to chlorinate fresh benzene as it arrives in the apparatus, drawing off the chloridine are prepared, and from these nitroanisidine, guaiacol, and vanilin are obtained.

The para derivative is the raw material for the manufacture of paranitraniline, formerly prepared by the nitration of acetanilide. It can also be prepared from paranitrophenol and its derivatives.

By dinitration dinitrochlorobenzene 1:2:4, melting at 50° C., is obtained, and this, as already stated, is the raw material for dinitrophenol.

Finally, by tri-nitration, picryl chloride is obtained. This nitration is effected with difficulty, and has found only a very restricted employment. By the hydrolysis of this chloride, picric acid is obtained, but this process seems without technical interest, as it is much easier to prepare the explosive by the trinitration of phenol.

These particulars show the importance of chlorobenzene, the manufacture of which was almost exclusively German before the war, partly owing to the fact that Germany produced huge quantities of liquid chlorine, particularly suitable for synthetic work because of its purity and concentration. The war has led the Allied countries to commence the manufacture of this highly important product, and it is now produced in France, Italy, the United States, England and Switzerland.

As for the extent of the world-wide production, it may be estimated that about 6,000 tons of chlorobenzene are produced from which 15,000 tons of sulfur blacks are obtained. Reckoning another 4,000 tons for all other uses, the production may be put down as 10,000 tons, which is probably above the mark.

At first glance, this manufacture does not appear to offer any special difficulties, but it must be remarked that the technical details of the manufacture are almost non-existent. The majority of books on the subject merely give general indications, without any precision as to the exact method of production.

Technical Chlorination of Benzene

As remarked, the preparation of chloro-benzene is theoretically simple. If the manufacturer has liquid chlorine and crystallisable benzene at his disposal, all that is required is to let the first agent react on the second in the presence of a catalyst—metallic iron for instance, to obtain the reaction already formularised:—

$$C_6H_6 + 2\,Cl = C_6H_5Cl + HCl.$$

This reaction leads to a considerable evolution of heat. It is, therefore, necessary to cool energetically to avoid loss of benzene by evaporation, the more so as the hydrochloric acid liberated also leads to losses if apparatus for the condensation and recovery of the volatile products is not provided. Moreover, an elevation of temperature brings about dichlorination of the benzene, even in the presence of unchanged benzene. It does not seem possible to prepare chlorobenzene exclusively when working with the correct theoretical proportions. A mixture of chlorobenzene with the dichloride is always obtained and a quantity of benzene remains unchanged.

Chlorination, therefore, differs notably from nitration and sulfonation, as in these operations the mono derivative is prepared almost exclusively, without the formation of sensible quantities of dinitrates or disulfonates. Possibly this is because chlorine reacts on benzene with much greater energy than nitric or sulfuric acid by reason of its great affinity for hydrogen.

Therefore, to limit the formation of the dichloride, which has no technical value, the reaction must be moderated by refrigeration, and the chlorination must be conducted in such a manner that there is always an excess of benzene. Practically, it suffices to carry the chlorination to about 60% of the theoretical calculation. As 78 parts of benzene require 71 parts of chlorine, the practice is to use 40 parts of chlorine. This corresponds to an increase of the weight of benzene of 20 parts, as only half of chlorine is fixed, and the other half combines with hydrogen and forms hydrochloric acid.

As an example, the following figures are tabulated, taken from three chlorination experiments, in the presence of 5% of iron, at a temperature not higher than 40° C.

	I.	II.	III.
Benzene	80	80	80
Increase of weight to	89	97	118

Benzene boils at 80.5° C., chlorobenzene at 132° C., paradichlorobenzene at 174° C. Fractional distillation of the three products above came out as follows:—

	I.	II.	III.
To 100° C.	60	35	—
100° to 120°	6	25	—
120° to 140°	23	28	50
Above 140°	—	—	60
Residue	—	9	8
	89	97	118

A fresh fractional distillation gave a neater separation in the second experiment, chlorinated to about 50%. The final results were 35 parts of recovered benzene, 10 parts partly chlorinated, 40 parts of chlorobenzene passing over between 128° and 134° C., and 5 to 10 parts of dichlorobenzene.

The third experiment is particularly characteristic; it shows that if the chlorination is pushed on until the benzene completely disappears, there is a considerable proportion of dichlorobenezene formed.

It will be seen, therefore, that it is necessary to work with the benzene always in excess in order to avoid as far as possible the formation of the dichloride, which is almost valueless. The chloro-benzene is then separated by distillation, and the recovered benzene is chlorinated anew, observing the same precautions as before. In this way, almost all the benzene is transformed into chlorobenzene, and any material proportion of the dichloride is avoided.

Apparatus

Apparatus for the chlorination of benzene is comparatively simple. A standard type is that invented by Marckwald and patented in 1902.

The fundamental idea is to chlorinate benzene as it arrives in the apparatus, drawing off the chlorinated product as it is formed.

The benzol is run into a still surmounted by a column, and provided with a refrigerator, so that the condensed benzene comes into the chlorination chamber at the desired temperature.

The flow of chlorine from a cylinder of liquified chlorine, regulated so as to allow the benzene always to be in excess. The hydrochloric acid formed escapes by a pipe at the top of the chlorination apparatus. As soon as the liquid attains a certain height in the chlorination chamber it is evacuated automatically by a conduit to the still. By proper regulation, the inflow of the benzene and the outflow of the chlorinated product should be equal. Owing to the column and the condenser, only the vapors of benzene arrive after condensation in the chlorinating chamber. As the content of this is much less than that of the still, it is possible to chlorinate almost all the benzene, and, at the same time, to avoid the formation of polychlorides. The major part of the benzene being transformed into chlorobenzene, all that is necessary is to evacuate the chlorination apparatus, and to proceed with the neutralization and distillation.

When the benzene is chlorinated to the degree required, it is distilled, and the diverse fractions are collected. The catalyst remains unchanged in the retort, and serves for a new operation, and the first fractions of benzene are again chlorinated.

A German patent claims that it is advantageous to employ a mixture of oxide of iron and metallic iron as catalyst. With this catalyst there is only a slight elevation of temperature, and there is no necessity to refrigerate.

Marckwald states that for 300 lbs. of benzene, 1 lb. of ferric chloride and 1 lb. of iron, in fine particles, are required, and the benzene is treated with 156 lbs. of chlorine. At the termination of the chlorination, a vacuum is produced, and the distillation follows. In this way, 205 lbs. of chlorobenzene, boiling at 131° to 133° C, is obtained. In addition, there is a fraction consisting of 145 lbs. of a mixture of benzene and chlorobenzene, which is treated again with 30 lbs. of chlorine. This yields 90 lbs. of chlorobenzene, and another fraction of mixed benzene and chlorobenzene of 55 lbs., from which 30 lbs. of chlorobenzene in turn is recovered.

To sum up, by using 300 lbs. of benzene, and employing 230 lbs. of chlorine, 335 lbs. of pure chlorobenzene, 24 lbs. of paradichlorobenzene, and 13 lbs. of sub-products are obtained. In addition there are 115 lbs. of gaseous hydrochloric acid, which yields 380 lbs. of hydrochloric acid at 20°.—*La Revue des Produits Chimiques.*

Plans for Chemical Show

(*Concluded from page* 348)

well as to the assembled delegates.

The exposition is a war-time necessity and regarding it as such each exhibitor is planning his exhibit so that it will be of the greatest benefit to the country through the men who visit it, all of whom are bent upon a serious purpose—that of producing war materials in large quantities, and constantly increasing this production till the war has been won by the United States and its allies.

Papers covering practically every phase of chemistry and a discussion of steps that will need to be taken after the war, will be presented by leading experts in each branch. Pressing chemical problems concerning many of the chief articles of domestic and foreign commerce will be taken up during the convention, and it is expected these discussions will have an important bearing on the future manufacture of materials that have been scarce and high-priced ever since the curtailment of American commerce with Germany and other European countries. In order to fill the demands for chemicals hundreds of factories have sprung up in various parts of the country, and while doing a large business, it is pointed out by experts that there is a lack of preparation to meet new conditions which are bound to follow at the close of the war.

Will Add to Plant.

At an estimated cost of $50,000 the Nitrogenus Chemical Co., Philadelphia, Pa., will erect a two-story concrete and brick addition to its factory at 37th and Tasker Sts.

Capt. Schlotz Now on Active Duty.

Active duty as captain in the Engineer Officers' Reserve will be taken up by Herman F. Schlotz, assistant chief engineer of the Newport Hydro Carbon Co. and the Newport Chemical Works, Inc., at Carrollville, Wis.

WANTED—Chemist; female, analytical and research. Apply during business hours, or phone Ossining 1057 for an interview. Ossining Chemical Works, Ossining, N. Y.

WANTED—Organic Chemist, of high caliber; must have had experience in research, plant design and plant operation, a man of character and ambition required, who can qualify for responsible position in growing organization within thirty miles of New York City. Initial salary up to five thousand, depending on qualifications. State nationality and necessary details, which will be held in strict confidence. Box J. C., c/o Chemical Engineer.

CHEMIST for position as factory manager; must have thorough training in chemical engineering; draft exempt; best of references required; good salary with excellent chances for advancement. Apply Mangano Manufacturing Co., 17 Seminary Ave., Rahway, N. J.

Glass Cloth—Glass Wool
and everything in the line of spun glass.

The glass cloth made entirely of glass, or with wire or silk warp, which we are now manufacturing, can be used for all insulation purposes; storage batteries, etc., etc.; where fireproof articles are required, such as curtains, draperies, hangings for hotels, theatres and public places; for diffusing light in moving picture studios, etc., etc.; for filtering and straining acids, etc.

Inquire at once about this new product and its application to your work.

There is one army more powerful than all the cannon on earth! It is behind the counters of the retail stores of this country.

Are you in command of part of it, you owner, manager or director of a retail business? You certainly are and you must launch it against the Powers of Evil now intent upon the destruction of everything worth your while as a business man.

SELL WAR SAVINGS STAMPS

Money will win this war and nothing else will. Valor without equipment is of no avail. Strategy without strength is of no avail. Money loaned our Government will assure them all for our armies—ships, guns, munitions, food, clothing, medicine, hospitals.

Give the order. Your salespeople will do the rest. They are fighters every one. They couldn't be soldiers in the greatest army in the world if they were not—the army of retail salespeople.

Gas

(Concluded from page 342)

The Detroit "Combination" Gas Machine is a very simple machine, comprising an air blower (either in the weight or water driven type), an automatic mixing regulator which is usually located in the basement of the building, and a carburetor or generator which also serves as a storage tank, and is usually located about 30 feet from the building and buried underground.

This plant uses gasoline as fuel. By observing the illustration of the machine the reader will notice the air blower, which is either weight driven or water driven, takes air from outside and forces it through the carburetor or generator where it passes over the surface of the gasoline in the various cells, two, three or more, depending upon capacity of machine—the gasoline exposed to the air vaporizes in the form of gas and is returned to the combination mixing regulator, where it is diluted with air and delivered to the burners in a fixed quality.

The weight and water driven machine differs only in respect to air blower. The weight type requires an occasional winding, the water driven requires no attention at all—it's automatic.

The company advises us that these gas plants passed the experimental stage long ago, that they have been making these machines for the past 50 years, and have over 30,000 in daily use.

Any of our readers who are interested in investigating these gas machines should communicate direct with the Detroit Heating & Lighting Co., Detroit, who will be glad to send a general catalog describing the plants in detail. This is a very elaborate catalog. It is not only a complete treatise on the manufacture of cold-process gasoline-gas, but it gives names of users of these plants in practically all parts of the country, thus enabling intending purchasers to see plants in operation.

Abraham L. Konwiser Resigns.

Following the resignation of Mr. Abraham L. Konwiser as supervisor of the analytical laboratory of the Metal and Thermit Corporation's plant at Chrome, N. J., Mr. Alexander Orschefsky has been appointed to take charge.

ULTRA VIOLET LIGHT

WHICH IS SUPERIOR TO ANY SIMILAR SOURCE

THE FACTS

about R. U. V. ultra violet ray lamps

The type illustrated above yields 2½ times the usual ultra violet ray component.
It operates on 220 volts D. C.
It is especially designed for laboratory use.
It employs no mercury vapor chamber at the anode end.
Its wave lengths have been measured as low as .18 u., which means *greater activity.*
Its frame is composed entirely of *new* and exceptionally clear quartz, thereby eliminating the loss of efficiency frequently resulting from reworked quartz.
It constitutes the final answer in all cases where experiments with ultra violet light have *failed* because the *source of rays was insufficient.*

Own and Offer

DRYERS

1—Direct Heat Rotary Dryer, 5'6"x40' complete with mechanical stoker.
1—Direct Heat Rotary Dryer, 5'6"x40' complete.
1—Direct Heat Rotary Dryer 3'x30' complete with stack.
1—Direct Heat Rotary Dryer 3'x18' complete.
1—Direct Heat Rotary Dryer, 3'x15' portable and self contained with oil tank, burner and stack complete.
1—Direct Heat Rotary Dryer 20"x9' complete.
1—Ruggles-Coles B2 Double Shell, Indirect Heat, Rotary Dryer 4'x21'.
1—Louisville Rotary Steam Heated Dryer 5'x20' complete.
1—Louisville Rotary Steam Heated Dryer 6'x25' complete.
1—Ord Standard 72" Fertilizer Cooker or Dryer with steam jacket and stirrer.

KILNS

1—Rotary 6'x60' complete with stack.
1—Rotary 5'x48' complete with lining.
1—Rotary 5½'x50' complete with lining.

MILLS

1—Tube Mill 4'x22' complete with silex lining, pebbles and automatic feeder.
1—Tube Mill 4'x10' complete with silex lining, pebbles and automatic feeder.
1—6'x22" Hardinge Conical Ball Mill, with lining, pebbles and automatic feed.
1—6'x9' Tube Mill, with lining, pebbles and automatic feed.
1—28" Schultz-O'Neill Pulverizer with dust collector and piping.

PRESSES

3—500 Ton Hydraulic Garbage Presses.
1—Hydraulic Scrap Press, new, 24" ram x 30" movement, with iron basket and pump.

EVAPORATORS

1—Double Effect Kestner Evaporator with 14 1½"x22'0" brass tubes in each effect.
1—Double Effect Evaporator with 100 1¼"x7' copper tubes in each effect. Horizontal type.
1—Double Effect Chrytalizer with stirrers, coils, and salt filters.

FILTER PRESSES

1—Sweetland Filter Press, 24" diameter, 29 plates.

TANKS, STILLS and KETTLES

1—Copper Six Section Still 3'x26' with coil condenser and copper dephlamator.
1—Reflux Condenser 3' diameter x 22" deep.
2—Jacketed, Agitated Open Top Kettles, 4'6"x7'x5/16" steel.
2—Cone Bottom Tanks or Digestors 6'x10'6"x½", manhole in cover and drop door at bottom.
1—Flat Bottom Tank or Digestor 4'x7x⅜", door in top. Grate and cleaning door near bottom.
1—Round Bottom, Open Top Cast Iron Kettle 72"x36"x½".
2—Duriron Cauldrons, 38" diameter x 22" deep.
6—Round Closed Copper Tanks, 300 gal., 500 gal., and 950 gal.

TANKS

1—Square Tank 12' long x 8' wide x 7' deep x 5/16"—5,000 gal. cap.
14—Square Tanks 12' long x 10' wide x 8' deep x 5/16"—7,200 gal. cap.
3—Square Tanks 10' long x 10' wide x 6' deep x 5/16"—4,500 gal. cap.
2—Square Tanks 25' long x 6' wide x 6' deep x 5/16"—6,750 gal. cap.
10—Square Tanks 17'6" long, x 10' wide x 5'6" deep x 5/16"—7,200 gal. cap.
3—Square Tanks 10' long x 9' wide x 6' deep x 5/16"—4,000 gal. cap.
1—Square Tank 15' long x 8'6" wide x 7'6" deep x 5/16"—7,200 gal. cap.
1—Square Tank 21'6" long x 7'6" wide x 7'6" deep x 5/16"—9,000 gal. cap.
2—Square Tanks 10' long x 10' wide x 7' deep x 5/16"—5,250 gal. cap.
3—Square Tanks 12' long x 12' wide x 8' deep x 5/16"—8,640 gal. cap.
4—Square Tanks 12' long x 12' wide x 6'4" deep x 5/16"—6,830 gal. cap.
1—Square Tank 10' long x 8' wide x 6'3" deep x 5/16"—3,750 gal. cap.
1—Square Tank 45' long x 7' wide x 7' deep x 5/16"—16,500 gal. cap.
1—Cylindrical Closed Tank, 44' diam. x 32' high—364,000 gal. cap.

Bottom—⅜" steel; first course, 7/16" steel; second and third courses, ⅜" steel; fourth, fifth and sixth courses, 5/16" steel. Top—No. 10 gauge steel.

Tanks are in first-class condition. Tanks are heavily reinforced with angle iron and tierods. Will quote attractive prices f. o. b. cars or barge Brooklyn, N. Y.

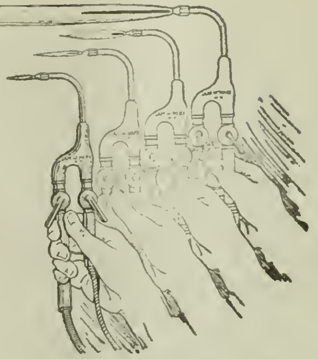
1—Closed Tank 4'2"x7'x5/16" with stuffing boxes in ends for shaft.
1—Open Steel Tank 21'6"x15', ½" and ⅝" stock.
1—Open Steel Tank 5'x6', ¼" steel.
1—Closed Steel Tank 9'6"x10', ¼" steel, manhole in cover.
2—Open Tanks 8'x8'x6'.

MISCELLANEOUS

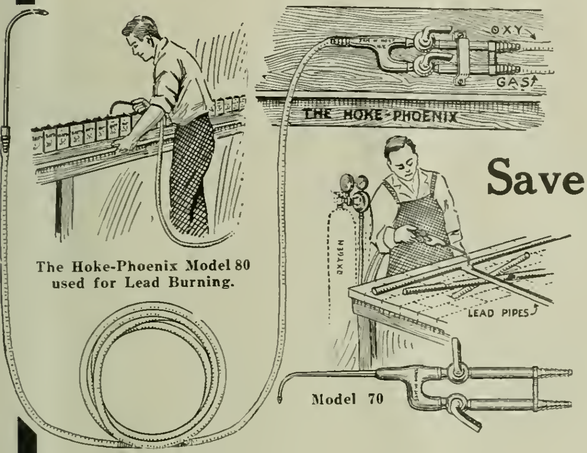
1—Steel Cylinder 78"x108'x¾'. Good for 200 lbs. pr. Doors at each end. Track and car inside.
1—Complete Cotton Seed Oil Plant.
1—Two Stage Clayton, Steam Driven Air Compressor, 7"x10"x8"
1—Fertilizer Screen, 1" mesh, 5'x14'6" with shaft 5"x19', with bearings, chain and sprocket for driving.

Fuller description given upon request.
We are interested in the purchase of chemical apparatus.

Every Shop and Laboratory Needs a Hoke-Phoenix



Various Flames of the Hoke-Phoenix Model 70.



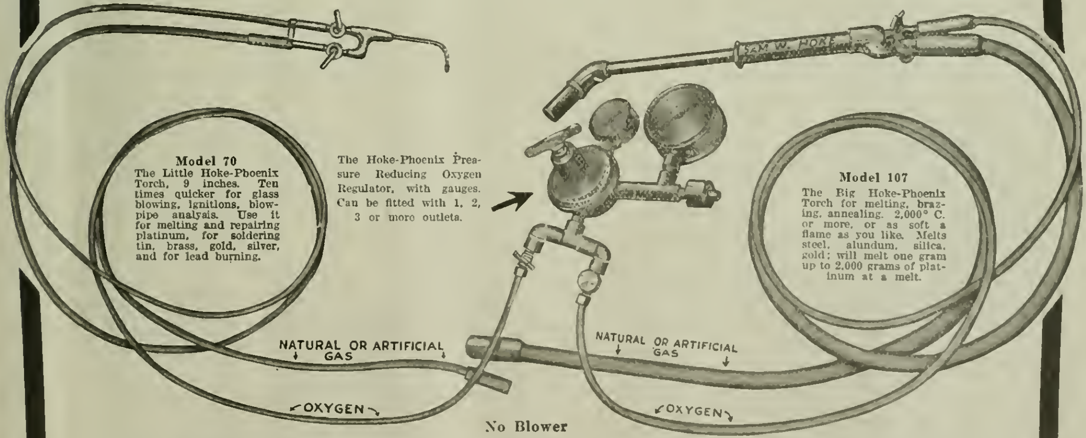
The Hoke-Phoenix Model 80 used for Lead Burning.

Model 70

Save Time

By using the Hoke-Phoenix Torches **whenever you need heat.** A sharp needle-like flame, hot enough to melt platinum or fuse silica, or a wide soft slow flame for gentle ignition.

For delicate or coarse glass-blowing; for every kind of fusion; for heating solutions QUICKLY. It does ordinary blowpipe or blastlamp work in a fraction of the time. Oxidizing or reducing flame; no blower, less noise; instant adjustment. Save time!



Model 70
The Little Hoke-Phoenix Torch, 9 inches. Ten times quicker for glass blowing, ignitions, blowpipe analysis. Use it for melting and repairing platinum, for soldering tin, brass, gold, silver, and for lead burning.

The Hoke-Phoenix Pressure Reducing Oxygen Regulator, with gauges. Can be fitted with 1, 2, 3 or more outlets.

Model 107
The Big Hoke-Phoenix Torch for melting, brazing, annealing. 2,000° C. or more, or as soft a flame as you like. Melts steel, alundum, silica, gold; will melt one gram up to 2,000 grams of platinum at a melt.

No Blower

Chemists—Metallurgists—Dentists—Jewelers—Shop Mechanicians—everybody that uses a flame—Use a Hoke-Phoenix Torch. They use ordinary gas at ordinary pressure, in connection with oxygen. They do everything that a Bunsen or blast lamp does in a fraction of the time; they do almost everything that the oxy-acetylene flame does, more cheaply and more safely.

Pay Us a Visit.

To all our readers and to visitors at the Chemical Show, the staff of The Chemical Engineer extends a cordial invitation to visit us at Booth 465, located at the extreme rear of the third floor (take elevator), close to the entrance of the Motion Picture and Conference Hall. Here a reception booth will be maintained, and all are invited to make this their headquarters with the full assurance of a hearty welcome, coupled with what services or information about the show we are able to furnish.

"Magic 4"

Before the next issue of this journal is in the hands of its readers it will be too late for you to change your decision regarding the amount of your investment in the safest securities obtainable anywhere in the world today. The Fourth Liberty Loan and the Fourth National Exposition of Chemical Industries are at hand. Both eclipse their predecessors in magnitude and importance, and if there yet remains any virtue in the traditional "Magic 4," the results of both should be most happy.

Already the hope has been expressed that the Fourth Liberty Loan may prove a Victory Loan. Predictions are rife, but these may safely be left in the hands of the military experts who write for the daily papers. There need be no speculation to cloud the issue in the minds of all the rest of us. The main object is to get behind this loan and push it with all the strength of a pocketbook which, but for the able protection of the Government which now asks *your* help, would have been practically non-existent months ago.

And should this indeed prove a Victory Loan, the opportunity of a lifetime to show that you appreciate the sacrifices being made hourly for you, will be gone forever. Our soldiers and sailors eagerly snap up Liberty Bonds to the limit of their financial resources, and during the last loan an East Indian potentate sent a fortune to Washington to be exchanged for Liberty Bonds, purely as a safe investment.

This is no time for quibbling. Uncle Sam needs money to protect *you*. You must do your part.

Facts About the Chemical Show This Year

It is estimated that some 25,000 chemists from all parts of this country, Canada, South America, and from a number of our Allied countries in Europe, are in New York to attend the Fourth National Exposition of Chemical Industries this year and the conventions being held in conjunction with it. It is at once the largest and most important exhibition of its kind ever held, and many new products are being shown for the first time.

More than 350 exhibits, representing every field of industrial chemistry and chemical manufacture are on display and are being demonstrated, while the pres-

(*See second page following.*)

PROGRAM AND TIME SCHEDULE

The Sign of ◎ Achievement

Fourth National Exposition of Chemical Industries

Grand Central Palace, New York, September 23-28

MONDAY, SEPTEMEBR 23.

Evening—Opening Addresses: Dr. C. H. Herty, Chairman Exposition Advisory Committtee. Dr. Wm. H. Nichols, President American Chemical Society. Mr. F. J. Tone, President American Electrochemical Society. Dr. G. W. Thompson, President American Intstitute of Chemical Engineers.

TUESDAY, SEPTEMBER 24.

Afternoon—Symposium on Acids and Chemical Engineering: A. Hough, "Chemical Engineering in Explosives; T. N. T., T. N. A., Picric Acid, Nitrobenzol." E. J. Franke, "Developments of Nitric Acid Manufacture."

Evening—Motion Pictures.

WEDNESDAY, SEPTEMBER 25.

Afternoon—Symposium on Potash: C. A. Higgins, "Recovery of Potash from Kelp." Linn Bradley, "Recovery of Potash from Iron Blast Furnaces and Cement Kilns." John W. Hornsey, "Potash from Desert Lakes and Alunite." H. W. Morse, "Potash from Searles Lake."

Evening—Motion Pictures: Alkali Industries: 1. Electrical Precipitation of Potash from Cement Dust. (Research Corporation.) 2. Colloid Chemistry.

THURSDAY, SEPTEMBER 26.

Afternoon—Symposium on Ceramics—Meeting of the American Ceramics Society: L. E. Barringer, "Manufacturer of Electrical Porcelain." (Illustrated.) A. V. Bleininger, "Recent Development in the Ceramic Industries." H. Ries, "American Clays." F. A. Whitaker, "Manufacture of Stoneware." (Illustrated.) J. B. Shaw, "Fuel Conservation." S. C. Linberger, "Carborundum Refractories."

Evening—Motion Pictures: Glass Making (Corning Glass Works). The Making of Cut Glass (Ford). Manufacture of Eletcrical Porcelain (General Electrical Company). The Making of Pottery (Ford).

FRIDAY, SEPTEMBER 27.

Afternoon—Symposium on Metal Industries: Leonard Waldo, "Development of Magnesium Industry." Alcan Hirsch, "Ferrocerium Pyrophoric Alloys." Theodore Swann, "Ferromanganese." Joseph W. Richards, "Ferro-Alloys of Silicon, Tungsten, Uranium, Vanadium, Molybdenum and Titanium."

Evening—Motion Pictures.

SATURDAY, SEPTEMBER 28.

Afternoon—Symposium on Industrial Organic Chemistry: S. P. Sadtler, "Industrial Organic Chemistry and Its Progress." C. A. Higgins, "Kelp as a Source of Organic Solvents." G. H. Tomlinson, "Wood Waste as a Source of Ethyl Alcohol."

Evening—Motion Pictures.

Among other films that will be shown each evening of the week are the following:

OIL INDUSTRIES.

The Spirit of the Flowers—Esential Perfume Oils.
The Story of a Cake of Soap.
Light from the Rocks—Natural Gas.
Lake Asphalt Industry (Barber Asphalt Paving Co.).

ence of men prominent in chemical and industrial plants, in colleges and industrial schools, in government and civilian work, who have been marshalled for the exhibition, gives ample evidence that it has fulfilled its aim, namely, to function as an educational event without parallel in its own particular field.

Next Year?

It is indeed fortunate for exhibitors and visitors that the plans of the Government to take over the Grand Central Palace for war work did not interfere with the date set for this eagerly-awaited show, for a certain amount of confusion is always bound to result from an eleventh hour change of location. However, this is the last exhibition of any kind to be held in the Palace until after the war is over. Judging, however, from the daily reports of the activities of an Army which the Kaiser declared didn't exist in a country which "wouldn't fight," it begins to look as though the doors would open on the *Fifth* National Exposition of Chemical Industries in the usual place.

Watch for the "Bull's Eye!"

One of the fundamental objects of the Chemical Exposition since its inauguration has been to call attention to chemical products manufactured for the first time in this country subsequent to the bursting of the storm which shut off Germany's exportations of many needful things. But until the present show it was not possible to tell at a glance just which products displayed belonged to these more recent triumphs of America's industrial chemists. Now, however, the management has evolved a method for displaying such products in a manner better calculated to focus the attention of casual visitor and chemist alike, and accordingly each will be adorned by a label upon which is printed a bull's eye. This label, however, will appear only on the products themselves and not upon new machinery. Visitors to the show should watch for this bull's eye, for each one constitutes an order of merit for an American chemist and records a "direct hit" upon the supposedly impregnable armor of Germany's chemical industries.

Watch for this label

on exhibits at the show.

A Record of Achievement.

In view of the present international situation regarding chemical industries in general and their rapid growth in the United States during the period of the European war in particular, the exposition has a message to deliver emphasizing the opportunity which is now being presented to the American manufacturer: Necessity has spurred on many chemists, and just how far they have succeeded may be judged by the exhibits at the exposition. The American chemist has come to the front and has shattered in four years the "line" of the German chemist, which had been building for more than forty years. In other words, the camouflaged "veil of mystery" of the German chemists has been lifted by the American chemists, whose discoveries or "secerts," as the Germans called them, are not locked in the brain of one man, but are given to others for the betterment of the industry. At the exposition this getting together of science and industry, with timely addresses and motion pictures, the exchange of ideas is certain to benefit all those who attend, and its influence in bettering and increasing the national production will be strongly felt.

The poster for this year's Exposition is the work of Rudolph Funk, of Brooklyn, N. Y., and was selected from others submitted by students at Cooper Union, New York City.

Wide in Scope.

While the exposition brings manufacturers of machinery, equipment, products, and supplies together with men who are using them, its chief purpose is to show the people of the country that the chemists of America have made rapid advances the past year—greater than ever before in this country's history. The convention brings to light some of the marvelous results of recent research, and many engineers and experts who hold important positions in the advance of the chemical industry are among the speakers.

The advisory committee of the exposition is composed of Charles H. Herty, chairman; Raymond F. Bacon, L. H. Baekeland, Ellwood Henrick, Henry B. Faber, Bernard C. Hesse, A. D. Little, W. H. Nichols, R. P. Perry, H. C. Parmelee, G. W. Thompson, F. J Tone, T. B. Wagner, and M. C. Whitaker. Charles F. Roth and F. W. Payne are the managers. Dr. Bacon, of this committee, is now head of the Chemical Warfare Section of the National Army and a member of General Pershing's staff.

Some sections of the South again are sending exhibits, and Canada is taking the opporuntiy of presenting the materials it has available for development by the chemist and financier. Technical and business men over the country should give heed to these exhibits, since they will show how they can meet the wartime need. A section for the Glass and Ceramic Industry, with which the American Ceramic Society is co-operating, has been added.

Papers covering practically every phase of chemistry and a discussion of steps that will need to be taken after the war, are being presented by leading experts in each branch. Pressing chemical problems concerning many of the chief articles of domestic and foreign commerce will be taken up during the convention, and it is expected these discussions will have an important bearing on the future manufacture of materials that have been scarce and high-priced ever since the curtailment of American commerce with Germany and other European countries.

Program.

A complete program and time schedule of the expositon, including the speakers and their subjects, and motion pictures to be presented, together with a list of the exhibitors, will be found on other pages of this issue. Instead of remaining open from 11 a. m. until 11 p. m., as was the custom last year, the doors of the present exposition do not open until midday and close promptly at 10.30 o'clock each night.

Don't Delay Your Census Return!

As Director of the newly-organized Chemical Warfare Service, Maj. Gen. William L. Sibert is assisting the War Department in gathering additional information regarding the chemists of this country. The following letter and the accompanying census blank, which all chemists are requested to fill out upon receipt and return promptly are self-explanatory:

WAR DEPARTMENT
CHEMICAL WARFARE SERVICE
WASHINGTON, D. C.

September 1, 1918.

To the Chemists of the United States:

This is a chemical war; therefore the War Department must have immediately available all possible information regarding chemical materials and chemical man power. Of these two essential elements chemical man power has so far received less attention. The census of American chemists made by the American Chemical Society in 1917 has been of great assistance to the War Department. Without it the present state of progress of the United States in chemical warfare would have been impossible of attainment.

However, during the same period conditions have undergone rapid and radical changes. The old census, excellent as it was, is no longer completely adequate. With the organization of the Chemical Warfare Service as an independent branch of the War Department, unifying all the elements of chemical warfare, it is obvious that the War Department must have its own set of records on a matter so vital to its own success. Moreover, these records must contain information which a short time ago was apparently of little importance. The new census must be made primarily from the viewpoint of the military status of chemists.

The importance of a prompt return of the census blank, properly filled out, by every chemist of the country cannot be overstated. American chemists are presented at this moment with one of the greatest opportunities to serve their country by the simple process of answering this questionnaire with all possible speed.

Problems of Filtration Solved by Glass Cloth

A comparative novelty in the field of chemical engineering, but one which is expected to fill an important role in the continued advancement of our mastery of the many mechanical problems which confront the industrial chemist at every turn, is the application of glass cloth to processes involving filtration.

This material is a recent product of the experimental department of L. Reusche & Co., New York. It is the outgrowth of a discovery which makes possible the spinning of glass in endless lengths, instead of a maximum of about eighteen feet, as heretofore. The strands of spun glass were formerly woven in their original condition, which produced a somewhat rough surface, but subsequent experiments in braiding led to the production of a woven fabric in which the warp was braided and the "filler" unbraided. It found many applications, but the final achievement was marked by the manufacture of glass cloth composed entirely of braided strands.

Its use in filtration has not as yet been called to the attention of industrial chemists generally. Substituted for cloth or paper, its principal claim to distinction lies in the fact that it will outwear anything now in use. It does not deteriorate, as is the case with the two above-mentioned mediums, and it can be readily cleaned, which obviates the frequent replacing of cloths in filter presses.

Owing to its composition, it is capable of filtering all acids with the exception only of HFl., which attacks glass, and in tensile strength it meets all tests required of it under actual working conditions. It is produced in weaves of varying fineness and can be manufactured satisfactorily under a wide range of specifications for special uses. It has successfully withstood a pressure of 60 lbs. while employed in a filter press.

Chemical engineers who have inspected this product have in many cases divined uses for it in connection with their own work which are still unknown to the manufacturers, and have spoken enthusiastically of the results. As is usual with a new product of any kind, the full extent of its application in the chemical industries is not as yet determined, but already a number of technical men are experimenting with it, while additional tests of its application in various kinds of work are constantly being made in the laboratory of the producers.

New Blowpipes for the Laboratory and Shop.

A new method of securing high temperatures which has had a four-year practical demonstration in the metal trades, is now taking its place in the chemical industries. The method is based on the use of ordinary gas at ordinary pressure in connection with oxygen. The Hoke-Phoenix blowpipes and torches, made in a variety of styles and sizes, have been developed, and are being used for practically every purpose that requires heat quickly.

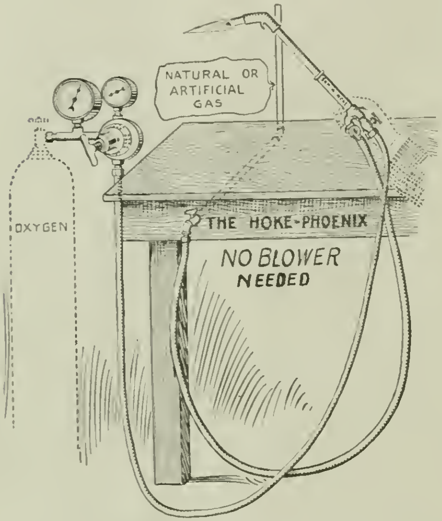
Originally designed for melting platinum, the Hoke-Phoenix blowpipes give a temperature of over 2000° C. (about 4000° F.). This melts silica, alundum, iridio-platinum, and most of the refractories on the market. But the flames are so readily adjusted that they can be used for lead burning, glass blowing, soft soldering, brazing, gentle ignitions, and so on. Either a soft, wide, slow flame, or a sharp needle-shaped flame, can be had by the adjustment of the needle valves or gas cocks with which each torch is provided.

Either an oxidizing or a reducing flame is obtained at will.

The special improvement offered by the Hoke-Phoenix is that it uses ordinary natural or artificial gas. This is not only much cheaper than acetylene, but vastly more convenient. Oxygen can be obtained almost anywhere. The Hoke-Phoenix will do almost everything that the oxy-acetylene will do, and certain things it will not do. But perhaps its greatest usefulness is as a time saver on work that can be performed with the slower air blast or Bunsen flame.

The large size Hoke-Phoenix blowpipes are used for such jobs as preheating, brazing big pieces, for melting platinum and gold, etc., for making up alloys, for annealing, tempering, and the like. Large quantities of solutions can be heated up quickly with them.

The smaller sizes will weld and solder the finest wire, including platinum wire, are most useful for glass blowing, repairing platinum and glass apparatus, for lead burning, and for blowpipe work of every kind. Many of the surgical instruments and brass buttons now being made for the Government are brazed or soldered with these small torches.



The Hoke-Phoenix torch outfit for melting metals.

The outfit comprises one or many torches, an oxygen regulator (pressure reducing valve) and the necessary tubing. The regulator serves to deliver the oxygens to the torches at exactly the right steady pressure, regardless of the pressure within the oxygen tank. Its gauges tell, respectively, how much oxygen is in the tank, and the pressure at which it is being delivered. In the few cases where ordinary gas cannot be obtained, tanks of hydrogen, acetylene, or compressed artificial gas, can be substituted.

One, two, or a dozen outlets can be connected to one regulator, so that any number of men can work at once, all from the same tank. Oxygen can be piped any distance.

It is claimed that the Hoke-Phoenix outfits save a great deal of time, are cheap and safe to operate, are easily handled and have a wide range of usefulness. They are made and sold by Sam W. Hoke, Mgr. Jewelers Technical Advice Co., 12 and 16 John street, New York.

C. E. Drayer Appointed Secretary of A. A. E.

The Board of Directors of the American Association of Engineers has announced to members and others the engagement of Mr. C. E. Drayer, of Cleveland, as National Secretary.

Mr. Drayer has been actively engaged in engineering society work of a local and national character for the past eight years. After graduating from college in Cleveland, Ohio, he served on western railroads until 1910, when he returned to Cleveland to become field engineer for the Nickel Plate Railroad on grade elimination work. He immediately joined the Cleveland Engineering Society and, as opportunity offered, took measures to advance the engineer in public esteem and to encourage him to train himself to be a leader in service to the community. After two years of marked success in the local society in Cleveland, he began to carry the message of progress to other societies and in time addressed most of the engineering organizations east of the Mississippi. In 1915 he became associated with Dr. F. H. Newell in forming the Committee on Engineering Cooperation, of which he is secretary. He organized and is secretary of the Ohio Association of Technical Societies. He is co-editor of "Engineering as a Career," a series of articles of advice to young men. For several years he was editorial correspondent for "Engineering News" and "Engineering News Record," where most of his articles on engineering society organizations have appeared. He served the Cleveland Engineering Society as its secretary for two years and was a member of its Executive Board when elected Secretary of the American Association of Engineers. He formulated the plan of combining the membership of the American Association of Engineers and Cleveland Engineering Society which promises to have a profound influence on engineering organization.

New Benzol Plant.

The Phillips Sheet & Pin Plate Co., Weirton, W. Va., expect to complete a plant for the production of benzol within the next year. The greater portion of their output will be furnished the U. S. Government for the manufacture of explosives.

Would Represent American Fi [illegible]

Announcement has been made by W. [illegible] & Co., London, chemical merchants and ma [illegible] chemists, that they are prepared to act as [illegible] buying agents and to represent American fir [illegible] in the heavy or fine chemical line.

Zaremba Offices Migrate.

The Zaremba Co., manufacturers of heavy [illegible] cal apparatus, have announced the removal of [illegible] offices to the Niagara Life Insurance Buil [illegible] Franklin and Mohawk streets, Buffalo, N. Y.

THE RECOVERY OF LIGHT OILS AND REFINING OF TOLUOL

Prepared by the U. S. Bureau of Standards*

Foreword.

This report has been prepared by the Bureau of Standards in response to the numerous inquiries for information regarding recovery of light oils and the refining of toluol. It has been submitted to, and revised in accordance with suggestions of, the committee organized under the chairmanship of Dr. E. R. Rosa of the Bureau of Standards at the request of the conference which met at the Bureau July 31, August 1 and 2. This committee consists of representatives of the Public Service Commissions, municipalities, manufacturers of gas, and makers of toluol recovery equipment. The assistance and co-operation of this committee are gratefully acknowledged by the Bureau.

Part I. The Technical Relation of the Gas Industry to the Military Needs of the Nation.

1. *High Explosives Manufactured from Gas By-Products.*—The importance of high explosives in the present war has been amply demonstrated. While nearly all kinds of explosives are used in some way, those which are most in favor for filling high explosive shells are manufactured from benzol and toluol, which substances have their most important commercial source in manufactured gas of one kind or another. The gas industry thus becomes directly and vitally connected with the conduct of the war and a survey of the demands which will be made upon it, and its preparedness in a technical way to meet these demands, is very important at the present time.

2. *City Gas Plants Must Supplement Coke-Oven Production.*—The constituents of illuminating and fuel gas which are important in the manufacture of explosives at the present time are benzol and toluol, especially the latter. The removal of these constituents from the gas which is a by-product of coke-oven plants has been practiced for some time. Plants manufacturing city gas, however, have not generally removed these substances from the gas since they contribute to its light and heat giving qualities and the substitution of other substances to maintain the gas quality up to prescribed standards has not usually been considered profitable. Even now, although several months have elapsed since the United States entered the war, comparatively few city plants are equipped to recover these materials, but the prospects are that in the near future they must do so if the requirements for high explosives are as great as is anticipated. Major Burns of the Ordnance Department at the conference held at the Bureau of Standards on August 1 stated that the army is dependent upon toluol for the manufacture of T.N.T. for shell filler. The amount of toluol needed depends upon the number of men engaged and how engaged. The present estimates are that toluol for shell filler will be needed in the coming year for our own army, for the Allies, and the navy at a rate considerably in excess of the present or anticipated supplies from works under construction. There is at the present time about four million pounds per month of T.N.T. nitrating capacity and sufficient toluol is not now available to utilize it; it is therefore now impossible to place more orders for T.N.T. primarily because more toluol is not available. It is probable that any and all explosives including the picrates will be necessary eventually.

3. *Manufacturing Processes in Use in the United States.*—The manufactured gas distributed in the United States is of three principal kinds: Coal gas, carburetted water gas, and oil gas.

The manufacture of water gas consists essentially of an intermittent process in which a bed of anthracite coal or coke is brought to a high temperature by an air blast and then steam under pressure is blown through the fuel, forming carbon monoxide, hydrogen and a small amount of carbon dioxide, by reaction with the carbon in the fuel. The resultant gas, called blue water gas, has a heating value of approximately 300 B. t. u. per cubic foot and almost no luminosity when burned in an open flame; it is conducted into a fire-brick lined chamber called the carburetter, which contains staggered rows of fire bricks, called checker brick, heated to incandescence during the blow period. Gas oil or fuel oil is sprayed into the carburetter while the gas is passing through, forming an oil gas which enriches the blue water gas to any desired heating value or candlepower. Another checker-brick-filled chamber, called the superheater, converts most of the oil gas vapors into permanent gases, which will not condense again upon cooling. During the formation of the oil gas certain portions of the hydrocarbons which compose the oil are changed in their composition to form benzol, toluol, and related hydrocarbons, called aromatic compounds. Considerable tar is formed at the same time. This is condensed, scrubbed, and washed out of the gas by various means, but usually at a temperature which permits most of the aromatics to go forward with the gas. The sulphur in the gas is removed by iron oxide purifiers and the gas is metered and leaves the plant at, or slightly above, atmospheric temperature.

---

*Published by permission of the Director, Bureau of Standards.

The manufacture of coal gas is essentially different from that of water gas. In this process certain classes of bituminous coals are distilled in fireclay or silica retorts or ovens and the resulting gases are condensed. scrubbed, washed and purified to remove water vapor, tar, ammonia, and sulphur. As in the water gas process, certain of the hydrocarbons given off by the coal are transformed by the heat of the retort to aromatic compounds. A small part of these aromatics are washed out of the gas by the wash water and tar, but the larger part remains in the gas; in fact, the cooling of the gas is usually so regulated that most of these substances will remain in the gas to increase its heating value and candlepower. Coal gas retorts take a variety of forms; among these are coke ovens. chamber ovens, horizontal D-shaped retorts, vertical retorts, inclined retorts, etc. Even those of a given class differ among themselves in details of construction. In most of them the distillation is an intermittent process, but some continuous methods are used. In all these processes the gas produced consists of the same constituents in somewhat different proportions. The form of apparatus used in a given case depends largely upon economic considerations or is governed by certain special qualities which are desired in one or more of the products produced. In all of these coal-gas processes, coke remains in the retort after distillation. In some of them. as. for example. in coke ovens. coke is the principal product; but in city gas plants, gas is the chief product. The operation is carried out in any case to give most satisfactory qualties to the principal product and at the same time obtain as high yields and good quality as possible of the secondary or by-products.

Mixed gas is usually understood to be a mixture of carburetted water gas and coal or coke-oven gas. It is supplied in many cities in the United States where the requirements permit of a mixed gas being supplied.

The manufacturing installation for mixed gas is practically two complete installations, one for coal gas and one for carburetted water gas, with their auxiliary scrubbing, condensing. purifying, and metering apparatus, entirely independent and separate. The manufactured mixed gas, however, is stored in common holders and delivered through a single distribution system.

The coal and water gas thus supplement each other. The uniform, but more cumbersome coal-gas production furnishes coke as fuel for the water-gas plant; this in turn takes care of the irregularities of the output and where necessary increases the quality of the gas production, especially where a high candlepower standard is in force.

The oil-gas process is at present confined chiefly to the Pacific Coast states, where comparatively cheap oil and expensive coal make the coal- and water-gas processes less feasible. In oil gas manufacture, oil alone is used as fuel for heating the checker bricks of the fixing chambers and oil is sprayed by steam into the chambers where in contact with the bricks, lampblack and permanent gases are formed. In this process also, aromatic compounds are included among the constituents of the gas.

4. *Average Content of Light Oils in Various Gases.*—The amount of benzol and toluol formed in any one of these processes is by no means definite. It depends upon the operating conditions and the quality of the raw materials (coal or oil). It would therefore be impossible to predict exactly what the yield in a given case would be, but an extensive inquiry into the operation of several typical plants has given the following approximate figures for the various processes. These

Data from Twelve Plants Investigated.

Approximate yield of crude light oils.

Horizontal-retort coal gas	3 gal. per short ton coal carbonized
Coke-oven gas	2.6 " " " " " "
Continuous vertical-retort coal gas*	1.8 " " " " " "
Carburetted water gas	10% of volume of gas oil used.

Composition of Crude Light Oils.

	Benzol.	Toluol.	Solvent naphtha, wash oil, naphthalene, etc.	Paraffins.
Horizontal-retort coal gas	38%	16%	46%	Less than 2%**
Coke-oven gas	55	14	31	Less than 2%**
Continuous vertical-retort coal gas*	15	15	58	12%
Carburetted water gas	42	25	33	Less than 2%**

Yield of Pure Products.

	Toluol.	Benzol.
Horizontal-retort coal gas	1.32 gal. per short ton coal carbonized	0.45 gal. per short ton coal carb.
Coke-oven gas	1.47	0.35 "
Continuous vertical-retort coal gas	0.27 "	0.26 "
Carburetted water gas***	0.15 gas. per 1,000 cu. ft. of gas ft. of	0.07 gal. per 1,000 cu. ft. of gas.

---

* Results from only one continuous vertical installation included here.

** This amount may be exceeded under some operating conditions, but paraffins can usually be kept down to this figure except in unusual conditions or with certain fuels.

*** The yield is variable according to amount of oil used in manufacturing the gas, being equivalent to about 2.0, 2.2% of the gas oil used in the plants investigated, but perhaps only about 1.6 in many cases.

figures are averages of the results obtained in the several plants; individual results may vary widely from them in a particular case.

No specific data are available for the amounts of toluol present in oil gas, though it is understood that the oil gas distributed on the Pacific Coast contains at least as much toluol as does coal gas.

Assuming that a ton of coal gives 10,000 cubic feet of gas and that 3.5 to 4 gallons of gas oil are used per 1,000 cubic feet of carburetted water gas, it is evident from the table that the amount of toluol obtainable per 1,000 cubic feet of rich water gas is considerably greater than that obtainable from coal or coke-oven gas.

5. *Prospective Toluol Sources.*—It does not seem likely that it will become practicable in the near future for plants having outputs less than 100 million cubic feet per year to recover light oils. A survey of plants of that size and larger indicates that there are about 112 plants having an aggregate annual gas output of about 135 billions cubic feet, of which about 97 billions are water gas, 25 billions coal gas, and 13 billions oil gas. What annual output of toluol could be expected from washing all this gas is problematical. It seems, however, that at least 0.05 gallon of toluol per 1,000 cubic feet of gas could be expected, which would give a prospective toluol recovery from all these companies of about 7,000,000 gallons per year. It seems likely that with an adjustment of standards the benzol production from the same amount of gas would be between three and four times as much as the toluol production, or approximately 18,000,000 gallons. These yields are by no means the maximum obtainable, since the production in some existing plants is higher than 0.05 gallon of toluol per 1,000 cubic feet. A few of the plants included in this estimate are already recovering part of their toluol and benzol, but by far the greater part of the available supplies are not yet recovered.

Part II. Principles Underlying Benzol and Toluol Recovery.

1. *Relation to Gas Plant Operating Conditions.*—Benzol, toluol, and the related hydrocarbons, which collectively will be designated as light oils, are present in city gas as condensible vapors and are associated with other hydrocarbons of the olefine and paraffin series which possess many physical properties similar to them. To separate some of these substances, especially the paraffins, from the light oil by commercial methods is well nigh impossible, and therefore it is important so to control the conditions of gas manufacture that as little of these substances will be present in the light soils as is possible. The presence of more than 2 per cent. of paraffin compounds in toluol is said to make it unfit for the manufacture of explosives. Only by careful attention to the temperatures and other operating conditions maintained in the gas making process and by the use of suitable raw materials can the gas manufacturer be certain that the toluol obtained from his light oils will be salable; for example, in the recovery of light oils from water gas not only the temperature but the rate of oil injection, spacing of checker bricks, etc., all affect results. Dirty checker bricks are said to be a very common source of high paraffin content in the toluol produced. The favorable conditions can only be determined by trial in each particular case.

For the successful operation of plants in which partial or total rectification of the light oils is carried out careful technical control seems to be a prime essential. In smaller plants where only light oil is recovered technical supervision should be available in starting the plant and for such a time afterwards as will enable the regular operators to become familiar with the fundamentals of operation and establish a routine. It might be feasible for several small plants within a certain district to retain the services of a technical man who would divide his time among them, and make the more elaborate tests which are occasionally required for successful operation.

2. *Removal of Light Oils from the Gas.*—To recover light oils from the gas, the method now almost universally employed is to bring the gas into contact with an oil which has a solvent action upon the light oils. Oil washing of gas is accomplished by a variety of apparatus. In any case to obtain complete absorption it is necessary that an adequate amount of oil at a sufficiently low temperature be brought into contact with the gas. The temperature of the wash oil should not exceed 30° C (86°F). The temperatures obtainable in practice will, of course, depend upon the facilities available for cooling the oil. It is desirable to have the oil a little warmer than the gas to prevent condensation of water from the gas into the oil which gives trouble in the further stages of recovery. The amount of wash oil circulated through the washers will depend upon the amount of light oil vapors present in the gas, the temperature of the oil, the amount of gas to be washed, and the saturation of the wash oil which it is feasible to obtain. About 10 gallons of wash oil per 1,000 cubic feet of gas washed, seems to be an average figure.

The oil now usually employed for this purpose in this country is a petroleum distillate called from its color, "straw oil"; some plants use a creosote oil obtained from the distillation of coal tar. The choice seems to depend largely upon which is available in a given case. The qualifications which a wash oil should possess seem to be substantially as follows:

A creosote oil upon distillation should yield not to exceed 5 per cent. up to 200°C and not less than 90 per cent. between 200°C and 300°C. The oil should not contain more than 7 per cent. naphthalene and should not show any marked increase in viscosity down to 4°C. The oil should be as fluid as possible under the working conditions and should have as small capacity for heat as possible.

The characteristics of a straw oil for this purpose, as obtained from some operators, are substantially as follows:

(1) Specific gravity not less than .860 at 15.5°C.

(2) Flash point in open cup tester not less than 135°C.

(3) Viscosity in Saybolt viscosimeter at 37.7°C not more than 70 seconds.

(4) The pour test shall not be over — 1.1°C.

(5) When 500cc of the oil are distilled with steam at atmospheric pressure, collecting 500cc of condensed water, not over 5cc of oil shall have distilled over.

(6) The oil remaining after the steam distillation shall be poured into a 500cc cylinder and shall show no permanent emulsion.

(7) The oil shall not lose more than 10 per cent. by volume in washing with 2½ times its volume of 100 per cent. sulphuric acid, when vigorously agitated with acid for 5 minutes and allowed to stand for 2 hours.

Some operators claim to have successfully used ordinary gas oil or water-gas tar. It is claimed by other operators, however, that when gas oil is used the paraffin and olefine compounds in it are likely to contaminate the light oil and that on account of emulsification this oil soon becomes unfit for use. Water-gas tar, it is said, soon becomes too thick for use and soon leads to serious naphthalene deposits in the distribution system. The advantages claimed for these materials are their general availability and lower cost, and the fact that most gas companies already have adequate storage facilities for these materials.

3. *Stripping Wash Oil.*—To separate the light oils from the wash oil in which they are dissolved, some form of still is employed; the difference in boiling points makes possible the separation. In large plants there are used continuous stills, in which steam comes in contact with the wash oil and boils off the light oils. The light oil vapors together with the uncondensed portion of the steam ascend upward through a series of chambers, which will be described more in detail later. In their ascent they come in contact with descending wash oil carrying light oils which they assist in freeing. The light oil vapors together with some steam, naphthalene, sulphur compounds, etc., pass away from the still and are condensed. Some of the wash oil is also carried along with the light oils, and has to be separated in the subsequent treatment. In small plants either continuous or intermittent stills may be used.

4. *Refining.*—To obtain from the light oils those constituents which are in most demand, a further separation by distillation and chemical treatment is necessary. The light oil is distilled in some form of still, usually equipped with a rectifying column and dephlegmator or planer which will be described in more detail later. The latter apparatus acts as a partial condenser in which part of the vapor is condensed and falling downward through the rectifying column meets the ascending vapors and washes from them a portion of the high boiling constituents. Only the light low-boiling constituents are able to pass the dephlegmator uncondensed. What vapors shall be allowed to pass on to the condensers depends upon the temperature maintained at the dephlegmator. This temperature is regulated according to the particular oil which it is desired to separate from the light oil mixture at any particular stage of the distillation. By the use of the dephlegmator and rectifying column it is possible to obtain much more definite separation of the benzol, toluol, and other aromatics than would otherwise be possible. In making the first distillation of the light oil, it is usual to collect the distillate in three successive portions or fractions, making the "cuts" at predetermined temperatures. The first fraction is collected in containing vessel or receiver until the temperature at the top of the still is 100°C. This fraction is called crude benzol, since benzol is its chief constituent. The flow of distillate is then diverted into another receiver and collected until a temperature of 120°C is reached. This fraction is termed crude toluol, from its chief component. The fraction collected above 120°C is called crude solvent naphtha from the use to which it is put, as a solvent of various materials. The boiling point of pure benzol and pure toluol are 80° and 111°C respectively. It will be noted that one of the changes of fractions or cuts is made midway between these boiling points while the boiling point of pure toluol is midway between the other cuts.

That the first separation is by no means complete is shown by the following analysis, which is typical of a crude toluol fraction:

Benzol	11.1%
Toluol	64.4
Solvent	8.9
Residue, etc	15.6
	100.0

The above procedure is not universal. Some operators collect the crude benzol and toluol together and subsequently separate them. Some of the impurities present in the crude fractions have boiling points so close to those of benzol and toluol that they cannot be separated from them by distillation. To remove a certain class of these compounds, called olefines, the fractions are washed successively with strong sulphuric acid, caustic soda and water. The olefines form a thick tarry mass which settles out by gravity upon standing and is drawn off. The fractions are then redistilled in stills with very high rectifying columns and fractions are finally obtained which boil within a single degree of the temperature which have been determined as the boiling points of pure benzol, toluol, etc.

Some operators prefer to distil the toluol fraction from water gas light oils in a still without a rectifying column, previous to final distillation in a column still. The vapors from the still in this case pass directly through a condenser, coming out in liquid form.

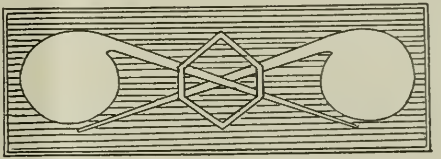
CHEMICAL WARFARE SERVICE

ITS HISTORY AND PERSONNEL

Watch for this insignia on the collars of uniformed men at the Chemical Show.



It designates a member of the newly-organized Chemical Warfare Service.

As far back as February, 1917, when it became thoroughly realized that in the event of war something must be done, and done quickly, if our soldiers were to enjoy adequate protection against the gas attacks of the Hun, and at the same time to be provided with the means for effective retaliation in kind, that a searching investigation of the myriad problems connected with the production and use of gas masks and poison gases was undertaken, after a conference with the War College, by a group of chemists and technicians working under the supervision of Director Van H. Manning of the U. S. Bureau of Mines.

Following the appointment later of the Committee on Gases by the National Research Council (April), and the subsequent appointment of the Advisory Board (November) headed by Dr. William H. Nichols, an experiment station was established in buildings of the American University in September of the same year. This station and work remained under the control of the Bureau of Mines.

The following month saw the creation of a Chemical Corps of the National Army, while coincidentally a body of chemical engineers who theretofore had been engaged in working on processes and plants for the manufacture of poison gases, was made a part of the Bureau of Ordnance of the War Department. It was this body of men which formed the foundation upon which the structure of the present Chemical Warfare Service was erected.

Subsequently, the experiment station at the American University was removed from the control of the Bureau of Mines and brought under the official wing of the War Department as a part of the then newly-organized Gas Defense Service. This was in keeping with the increasing determination of the Government to co-ordinate the efforts of our chemists. At the time of this transfer, a well-deserved tribute was vouchsafed the work of Dr. Manning and the staff of the Bureau of Mines by Secretary of War Baker in the following letter to the President:

War Department, Washington.
June 25, 1918.

My dear Mr. President:

In connection with the proposed transfer of the chemical section at American University from the Bureau of Mines to the newly constituted and consolidated Gas Service of the War Department, which you are considering, I am especially concerned to have you know how much the War Department appreciates the splendid services which have been rendered to the country and to the Army by the Department of the Interior, and especially by the Bureau of Mines under the direction of Dr. Manning. In the early days of preparation and organization, Dr. Manning's contact with scientific men throughout the country was indispensably valuable. He was able to summon from the universities and the technical laboratories of the country men of the highest quality and to inspire them with enthusiastic zeal in attacking new and difficult problems which had to be solved with the utmost speed. I do not see how the work could have been better done than he did it, and the present suggestion that the section now pass under the direction and control of the War Department grows out of the fact that the whole subject of gas warfare has assumed a fresh pressure and intensity, and the director of it must have the widest control so as to be able to use the resources at his command in the most effective way possible. The proposal does not involve the disruption of the fine group of scientific men Dr. Manning has brought together, but merely their transfer to General Sibert's direction.

Respectfully yours,
The President. (Signed) NEWTON D. BAKER.

This recognition of the part played by Dr. Manning and his workers in the development of the present organization was further amplified in a letter from President Wilson to the man whose foresight and initiative saved us so much valuable time:

White House, Washington.
26 June, 1918.

My dear Dr. Manning:

I have had before me for some days the question presented by the Secretary of War involving the transfer of the chemical section established by you at the American University from the Bureau of Mines to the newly organized Division of Gas Warfare in which the War Department is now concentrating all the various facilities for offensive and defensive gas operations. I am satisfied that a more efficient organization can be effected by having these various activities under one direction and control, and my hesitation about acting in the matter has grown only out of a reluctance to take away from the Bureau of Mines a piece of work which thus far it has so effectively performed. The Secretary of War has assured me of his own recognition of the splendid work you have been able to do, and I am taking the liberty of enclosing a letter which I have received from him, in order that you may see how fully the War Department recognizes the value of the services.

I am today signing the order directing the transfer. I want, however, to express to you my own appreciation of the fine and helpful piece of work which you have done, and to say that this sort of team work by the bureaus outside of the direct war-making agency, is one of the cheering and gratifying evidences of the way our official forces are inspired by the presence of a great national task.

Cordially yours,
(Signed) WOODROW WILSON.

Dr. Van H. Manning,
Chief, Bureau of Mines,
Department of the Interior.

EXECUTIVE ORDER.

It is hereby ordered that the Experiment Station at American University, Washington, D. C., which station has been established under the supervision of the Bureau of Mines, Interior Department, for the purpose of making gas investigations for the Army, under authority of appropriations made for the Ordnance and Medical Departments of the Army, together with the personnel thereof, be, and the same is hereby, placed under the control of the War Department for operation under the Director of Gas Service of the Army.

WOODROW WILSON.

The White House, 25 June, 1918.

Followed then the official organization of the Chemical Warfare Service, created through the issuance of General Order No. 62, U. S. War Department. The order follows:

GENERAL ORDERS, NO. 62.

CREATING CHEMICAL WARFARE SERVICE

War Department.
Washington, June 28, 1918.

I—(1) Under authority conferred by Sections 1, 2, 8 and 9 of the Act of Congress, "Authorizing the President to increase temporarily the military establishment of the United States," approved May 18, 1917, and the Act "Authorizing the President to co-ordinate or consolidate executive bureaus, agencies, and offices, and for other purposes, in the interest of economy and the more efficient concentration of the Government," approved May 28, 1918, in pursuance of which Act the President has issued an Executive Order dated June 25, 1918, placing the experiment station at American University under control of the War Department, the President directs that the gas service of the Army be organized into a Chemical Warfare Service, National Army, to include:

(a) The Chemical Service Section, National Army.

(b) All officers and enlisted men of the Ordnance Department and Sanitary Corps of the Medical Department as hereinafter more specifically specified (regular officers affected being detailed and not transferred).

(2) The officers for this service will be obtained as provided by the third paragraph of Section 1 and by Section 9 of the Act of May 18, 1917, the enlisted strength being raised and maintained by voluntary enlistment or draft.

(3) The rank, pay, and allowances of the enlisted men of the Chemical Warfare Service, National Army, shall be the same as now authorized for the corresponding grades in the Corps of Engineers.

(4) The head of the Chemical Warfare Service, National Army, shall be known as the Director of the Chemical Warfare Service, and, under the direction of the Secretary of War, as such, he shall be, and hereby is, charged with the duty of operating and maintaining or supervising the operation and maintenance of all plants engaged in the investigation, manufacture, or production of toxic gases, gas-defense appliances, the filling of gas shells, and proving grounds utilized in connection therewith and the necessary research connected with gas warfare, and he shall exercise, full, complete, and exclusive jurisdiction and control over the manufacture and production of toxic gases, gas-defense appliances, including gas-shell filling plants and proving grounds utilized in connection therewith, and all investigation and research work in connection with gas warfare, and to that end he shall forthwith assume control and jurisdiction over all pending Government projects having to do or connected with such manufacture, production, and operation of plants and proving grounds for the Army and heretofore conducted by the Medical Department and Ordnance Deparment under the jurisdiction of the Surgeon General and the Chief of Ordnance, respectively, and all material on hand for such investigation or research, manufacture or production, operation of plants and proving grounds and all lands, buildings, factories, warehouses, machinery, tools and appliances, and all other property, real, personal, or mixed, heretofore used in, or in connection with, the operation and maintenance of such plants and proving grounds for the purpose of investigation or research, manufacture or production, already procured and now held for such use by, or under the jurisdiction and control of, the Medical Department of the Ordnance Department, all books, records, files, and office equipment used by the Medical Department or the Ordnance Department in connection with such investigation or research, manufacture or production, or operation of plants and proving grounds, all rights under contract made by the Medical Department or Ordnance Department in, or in connection with, the operation of such plants and institutions as specified herein, all rights under contract made by the Medical Department or Ordnance Department in, or in connection

with, such work, and the entire personnel (commissioned, enlisted, and civilian) of the Ordnance Department and Sanitary Corps of the Medical Department as at present assigned to or engaged upon work in, or in connection with, such investigation or research, manufacture or production, or operation of plants and proving grounds, are hereby transferred from the jurisdiction of the Ordnance Department and the Medical Department and placed under the jurisdiction of the Director of the Chemical Warfare Service, it being the intention hereof to transfer from the jurisdiction of the Medical Department and the Ordnance Department to the jurisdiction of the Director of the Chemical Warfare Service every function, power, and duty connected with the investigation, manufacture, or production of toxic gases, gas-defense appliances, including the necessary research connected with gas warfare, gas-shell filling plants, and proving grounds utilized in connection therewith, all property of every sort or nature used or procured for use in, or in connection with, said operation of such plants and proving grounds and the entire personnel of the Ordnance Department and Sanitary Corps of the Medical Department as at present assigned to, or engaged upon work in, or in connection with, the operation and maintenance of such plants engaged in the investigation, manufacture, or production of toxic gases, gas-defense appliances, including gas-filling plants and proving grounds utilized in connection therewith.

(5) All unexpended funds of appropriations heretofore made for the Medical Department or Ordnance Department and already allotted for use in connection with the operation and maintenance of plants now engaged in, or under construction for the purpose of engaging in, the investigation, manufacture, or production of toxic gases or gas-defense appliances, including gas-shell filling plants, are hereby transferred to, and placed under the jurisdiction of, the Director of the Chemical Warfare Service for the purpose of meeting the obligations and expenditures authorized herein; and, in so far as such funds have not been already specifically allotted by the Medical Department and the Ordnance Department for the purposes specified herein, they shall now be allotted by the Secretary of War, in such proportions as shall to him seem best intended to meet the requirements of the situation and the intentions of Congress when making said appropriations, and the funds so allotted by the Secretary of War to meet the activities of the Chemical Warfare Service, as heretofore defined herein, are hereby transferred to, and placed under the jurisdiction of, the Director of the Chemical Warfare Service for the purpose of meeting the authorized obligations and expenditures of the Chemical Warfare Service.

(6) This order shall be and remain in full force and effect during the continuation of the present war and for six months after the termination thereof, by proclamation of the treaty of peace, or until theretofore amended, modified, or rescinded.

II—By direction of the President, Maj. Gen. William L. Sibert, United States Army, is relieved from duty as Director of the Gas Service, and is detailed as Director of the Chemical Warfare Service, National Army.

By Order of the Secretary of War.
[322.06 A. G. O.] PEYTON C. MARCH,
General, Chief of Staff
[Official] H. P. McCAIN,
The Adjutant General.

PERSONNEL OF C. W. S.

The following list of the heads of the various divisions and sections, together with the commissions thus far awarded, indicate the functions of each official and the manner in which the organization will be enabled to operate as a unit:

Director and Staff.

DIRECTOR.

Major General William L. Sibert.

STAFF.

Col. W. J. L. Lyster, S. C., Medical Officer; Capt. H. C. Bradley, Assistant.

Lt. Col. C. B. Thummel, O. D., Ordnance Officer; Maj. C. S. Stevenson, C. W. S., Assistant.

Maj J. H. Brightman, Representative of British Military Mission.

Headquarters Division.

ASSISTANT DIRECTOR.

Col. H. C. Newcomer, C. E.

(To act for the Director in his absence, in charge of all military matters and new projects. Chairman, Board of Review.)

Military Assistants.

Maj. J. H. Walton, C. W. S.; Capt. J. S. Baker, C. W. S.; Capt. V. L. Bohnson, C. W. S.; Capt. A. Bolenbaugh, C. W. S.; Capt. S. J. Delancy, C. W. S.; First Lt. R. C. Henderson, C. W. S.; Second Lt. F. C. Perkins.

Technical Assistants.

Maj. S. A. Tucker, C. W. S.; Capt. R. Franchot, Capt. G. M. S. Tait, C. W. S.; First Lt. L. Van Doren, C. W. S.

OFFICE ADMINISTRATION.

Maj. W. W. Parker, C. W. S.

(In charge of files and clerical personnel, receipt and distribution of mails, collection and transmission of papers between various sections of the office, office disbursements.)

Assistants.

First Lt. F. W. Dasher, C. W. S.; Second Lt. B. W. Tipton, C. W. S.; Second Lt. W. F. Kunkle, C. W. S.; Second Lt. W. D. Towler, C. W. S.

RELATIONS SECTION.

Col. M. T. Bogert, C. W. S.

(In charge of relations with Universities, with industries, with the office of the Director of Purchases, Storage and Traffic, and with the War Industries Board, including its committees.)

Assistants.

Maj. Victor Lenher, C. W. S.; Capt. C. V. Sheehan, C. W. S.; Maj. W. J. Noonan, C. W. S.; Capt. W. H. Hickin, C. W. S.; Maj. Allen Rogers, C. W. S.; First Lt. H. F. Scharer, C. W. S.; Maj. Samuel Avery, C. W. S.; Mr. Geo. S. Case, C. W. S.

PERSONNEL SECTION.

Maj. F. E. Breithut, C. W. S.

(In charge of all matters pertaining to procurement and assignments of commissioned and enlisted personnel of the Chemical Warfare Service.)

Assistants.

First Lt. G. W. Phillips, C. W. S.; First Lt. H. B. Bramlet, C. W. S.; Second Lt. A. E. Case, C. W. S.

CONTRACTS AND PATENTS SECTION.

Capt. W. K. Jackson, C. W. S.

(In charge of Section, Member of Board of Review.)

Assistant.

Capt. R. B. Meckley, C. W. S.

FINANCE SECTION.

Maj. C. C. Coombs.

(In charge of estimates, appropriations and allotments, of administrative audit of all disbursing accounts and of property. Member of Board of Review, C. W. S.)

Assistant.

Capt. Ben Jenkins, C. W. S.

REQUIREMENTS AND PROGRESS SECTION.

Capt. S. M. Cadwell, C. W. S.

(In charge of Section.)

Assistant.

Second Lt. J. A. Sohen, C. W. S.

CONFIDENTIAL INFORMATION SECTION.

Maj. S. P. Mulliken, C. W. S.

(In charge of Section.)

Assistant.

Second Lt. H. E. Moore, C. W. S.

TRANSPORTATION SECTION.

(Officer in charge not yet selected.)

Assistant.

Capt. H. R. Sharkey, C. W. S.

Field Organization.

GAS OFFENSE DIVISION.

Officer in Charge, Col. W. H. Walker.

(The production of gas, containers and other material for use in offensive gas warfare.)

GAS DEFENSE DIVISION.

Officer in Charge, Col. Bradley Dewey.

(The production of material such as gas masks for use in the defensive.)

PROVING DIVISION.

Officer in Charge, Maj. W. S. Bacon.

(Charged with the duty of proving the efficiency of material under field conditions.)

DEVELOPMENT DIVISION.

Chief, Col. Frank M. Dorsey.

(For the development of material received from the Research Division to the point where it may be turned over for proving.)

RESEARCH DIVISION.

Chief, Col. G. A. Burrell.

(Charged with research into all matters pertaining to gas warfare.)

EUROPEAN DIVISION.

(This division includes personnel assigned to all divisions and corps and army headquarters in addition to those required for the supply of material in the field in France.)

MEDICAL DIVISION.

Officer in Charge, Col. W. J. L. Lyster.

Commissioned Officers.

The Delora Co. Incorporated.

Chemicals, etc., will be manufactured by the recently incorporated Delora Co., New York City. The capital of the company is $250,000 and the incorporators are E. S. M. Selig, A. B. Crawford and F. Aranow.

Liberty Chemical Company.

The Liberty Chemical Company has been incorporated under the laws of New Jersey at Woodridge, that state, with a capital of $50,000 to manufacture chemicals. The incorporators are Victor L. King, Eugene C. King and Charles R. Ruegger.

American Woodpulp Now Has Chemical Plant.

Announcement has been made by the American Woodpulp Corporation, New York City, that in addition to its regular line of business there has been added to the plant a chemical department in charge of Alfred J. Marcus, formerly of the firm of Monnier & Marcus.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS[*]

Part XVII

Absorption of Ultra Violet Light.

Observations on the absorption of ultra violet light by compounds in a liquid or vaporous state have shown the invisible spectrum to be a means of examination of inorganic and organic bodies and probably one which the chemist ultimately will add to the usual routine of laboratory practice. Some extended and the ultra violet region have been made, especially in the field of organic chemistry. Bodies of different constitution reveal characteristic absorption spectra in many cases, isomeric compounds may be compared and double or triple bonding oriented to a considerable degree. The development of this little known field of investigation of the ultra violet ray, is therefore highly promising.

Determination of Small Quantities of Ozone.

Hallwachs (Ann. Physik. 1909 (iv), 30, 602) has shown that small quantities of ozone can be estimated photo-electrically by reason of the large specific absorptive power of the gas for ultra violet radiation of wave-length in the neighborhood of $258\mu\mu$. For such measurements the pressure of the gas in the absorption tube should be of the order of 0.01 mm. of mercury. On the assumption that the photoelectric effect is proportional to the intensity of the incident light, *Krüger* and *Mueller* (Physikal. Zeitsch., 1912, *13*, 729) have measured the absorption of ultra violet light of wave-length $\lambda = 254\mu\mu$ in ozonised oxygen with the aid of a photo-electric cell containing a potassium electrode in contact with hydrogen at a pressure of 0.3 mm. The results obtained with different samples are in good agreement with those found by the iodine method, and it is shown that the optical method can be employed for smaller concentrations than the chemical method, the lower limit being about 0.001 per cent. *Fabry* and *Buisson* (Compt. rend., 1913, *156*, 782) have made a determination of the variations of "a," the constant of absorption for ozone, as defined by the equation $I = I_0 10^{-ad}$, where I and I_0 are the intensities of the light before and after absorption, and d the thickness in centimeters of pure gaseous ozone, λ varying from 2,300 to 3,400. The maximum absorption takes place at λ 2,550, is very high at this point, and the absorption varies rapidly between 2,900 and 3,300, the value of "a" being given by $\log a = 17.58 - 0.00564\ \lambda$. From these results, combined with measurements made on the amount of light from the sun transmitted by the atmosphere, Fabry and Buisson draw the conclusion that the ozone content of the atmosphere, if evenly distributed, would be equal to 0.6 cubic centimeters per cubic meter of air.

Ozone and Sunlight.

Meyer (Ann. Physik., 1903, (iv), 12, 849) has determined the value of the absorption coefficient of ozone over the range $\lambda = 185\mu\mu$ to $\lambda = 300\mu\mu$, and finds a minimum value at $\lambda = 205\mu\mu$ and a maximum at $\lambda = 258\mu\mu$. The latter agrees with the position ($\lambda = 256\mu\mu$) of the absorption band given by Hartley (J. Chem. Soc., Trans., 1881, 39, 60, 111). The sun's spectrum comes more or less suddenly to an end at $\lambda = 293\mu\mu$, and the absorption of the solar radiation in the earth's atmosphere, which is responsible for that fact, is, according to Hartley, due to the ozone. Taking into account the percentage of ozone in the atmosphere and the values of the absorption coefficient obtained by himself, Meyer regards Hartley's views as probably correct.

Liquid Ozone.

By the evaporation of liquid ozone, a gas containing a high percentage of ozone is obtained, which is prone to explode. The absorption spectra of liquid and gaseous ozone have been examined photographically and thermoelectrically. *Ledanburg* and *Lehmann* (Chem. Centr., 1906, i, 1727; Ber. Deut. phys. Ges., *4*, 125) when using gaseous ozone in small concentrations found the absorption reached to about $316\mu\mu$ in the ultra violet, but as the concentration increased, new bands appeared and extended into the region of longer wave-length. Liquid ozone did not show any absorption bands in the visible spectrum and there were no bands in the ultra violet.

Absorption of Ultra Violet Rays by Tap-Water.

The observation that the electrical action of ultra violet light is diminished very much more by passing through tap-water than through distilled water led Pidduck (Phil. Mag., 1909, (iv), 17, 710) to examine the absorption power of dilute solutions. The dependence of the absorption on the concentration of the solution was investigated in the case of sodium chloride and potassium bromide, the latter salt being more active than the former. The absorption of light by water is changed by the presence of strongly hydrated salts, as shown by the radiometer, according to *Guy, Schaeffer* and *Jones* (J. Physikal. Zeitsch., 1913, 14, 278; Amer. Chem. J., 1913, 49, 265; J. Chem. Soc. 1913, Abs. *104*, ii, 362).

Hydrogen Peroxide.

Various authors have observed the presence of hydrogen peroxide in solutions of radioactive salts, but, in considering the absorption of ultra violet light by radioactive elements and their degradation products, Zelinsky regarded the part played by the hydrogen peroxide formed under the influence of radium as small. *Rosanoff* (J. Russ. Phys. Chem. Soc., 1912, *44*, 1146; J. Chem. Soc. 1912, Abs. 102, ii, 875) investigated the absorption spectra of ultraviolet light by solution of hydrogen peroxide of various concentrations, and draws the conclusion that it is highly probable that the absorption of short waves by radioactive substances is conditioned by two factors: by the emanation developed, and, to a considerable extent, by the hydrogen peroxide formed under the influence of this emanation. As these two factors exist together, it is difficult to decide which of them plays the larger part in the absorption. The magnitude of the absorption may be taken as a measure of the degree of activity of the substance only when this is used in the solid state.

Iodine.

The absorption spectrum of iodine has been examined by *Wood* (Phil. Mag., 1912 (vi), 24, 673; J. Chem. Soc., 1912, Abs., 102, ii, 1018) with the aid of a spectrograph of very high resolving power, with the result that the visible region is found to contain a vast number of lines, which is estimated at more than 50,000. The sodium and bromine absorption spectra are equally complex, and it would appear that a large number of lines in the bromine and iodine spectra are coincident. This may be due to the occurrence of identical systems of electrons in the two elements, giving rise to the same series of frequencies.

The resonance spectra of iodine excited by the green and yellow lines of mercury have been further examined by *Wood* (Phil Mag., 1913 (iv), 26, 828; J. Chem. Soc., 1913, 104, ii, 994). By operating the mercury vapor lamp with different resistances in circuit it was found possible to vary the width of the exciting line so as to cover a variable number of iodine absorption lines, and the resonance spectra obtained under these circumstances have been carefully compared. In the earlier work it was assumed that each of the bright resonance lines coincided with one or other of the numerous absorption lines, but it is now found that this is not the case. The vapor always emits a line, the wave-length of which is identical with that of the exciting light. This line, termed the resonance radiation line, is accompanied by companion lines which form a group very similar in appearance to the other groups which appear at intervals along the spectrum. by reducing the density of the iodine vapor in the resonance tube it is found that the band spectrum is emitted. This spectrum is more strongly absorbed by the iodine vapor than the lines of the resonance groups. There is apparently no phosphorescent effect in the emission of the resonance spectrum.

Ribaud (Compt. rend. 1913, 157, 1065) has measured the co-efficients of absorption of bromine vapor in ultra violet light by taking two photographs side by side with the same duration of exposure, one having passed through the bromine, and the other having the intensity of light reduced in a known ratio, and seeking in the two photographs the region where the blackness is the same, thus getting the co-efficient of reduction and the index of extinction for the given wave-length. Measurements were made with the bromine vapor under various pressures, the results showing that the index of extinction is proportional to the pressure. Ribaud considers that the kinetic theory of absorption does not hold good for broad bands, but for the fine rays it accounts for the facts observed.

A study of the ultra violet absorption spectra of sulphur dioxide sulphurous acid and its salts and esters, hypochlorous acids and its salts and esters, chlorine dioxide, chlorous acid and the chlorites, and nitric acid, nitrates and alkyl nitrates, has been made by *Schaefer* (with Higgemann and Köhler) (Zeitsch. Elektrochem., 1915, 21, 181) over a large range of concentration and variation of experimental conditions.

Sulphurous Acid and Sulphites.

Garrett (J. Chem. Soc., Trans., 1915, 107, 1324) has made the extinction measurements with solutions of sulphurous acid, rubidium hydrogen sulphite, potassium hydrogen sulphite, sodium sulphite, ammonium sulphite, sodium metabisulphite, potassium metabisulphite, acetone sodium hydrogen sulphite, potassium sodium sulphite, sodium sulphite and symmetrical and unsymmetrical diethyl sulphites. These measurements were made with a Hilger quartz spectrometer and a nickel spark as illumination.

Ultra Violet Absorption of Sodium Vapor.

The ultra violet absorption spectrum of sodium vapor consists of a Balmer series of lines, of which *Wood* (Phil. Bag., 1918 (iv), *16*, 945; J. Chem. Soc., 1909, Abs., *96*, ii, 106), in his earlier work, photographed thirty, this making the longest Balmer series know. In this series the D-lines appear as the third member, while the end is at 2411. The photographs were obtained by passing the light from a cadmium spark through a steel tube about one meter long containing sodium vapor at dull-red heat under a nitrogen pressure of 15 centimeters. By making use of a large quartz spectrograph the Balmer series of double lines have been increased by Wood (Phil. Mag., 1909, *18*, 530; J. Chem. Soc., 1909, Abs., *96*, ii, 845) from thirty to forty-eight. The higher members of the series make their appearance as the density of the sodium vapor is increased, and simultaneously the lower members of the series are obliterated by channeled spectra which accompany them. These channeled spectra are analogous to that which accompanies the D-lines, but the constitution of the former is somewhat different, in that they spread out in both directions above and

Tanning Materials from Phenol

Edmund Stiasny, of Headingley, Leeds, England, assignor to the Badische Anilin and Soda Fabrik (Amer. Pat. 1,237,405, of Aug. 21,1917) describes a relatively simple method of transforming phenol and its homologues into active tanning agents. They result from condensing a monohydroxylated phenolic body with sulfuric acid and formaldehyde, under mild conditions, so that essentially products soluble in water are formed. The reaction can be effected either by treating a phenolic body with formaldehyde in the presence of dilute acid and then sulfonating the insoluble condensation products by treatment with strong sulfuric acid until they are soluble in water, or the reaction product of a phenolic body with concentrated sulfuric acid, or a phenol-sulfonic acid, or a mixture of a phenol and a phenol sulfonic acid, can be treated with formaldehyde. To avoid the formation of the known products which are insoluble in water and which may result by a violent action, care is to be taken that the process goes on under mild conditions, so as to cause a smooth reaction between the components. A rise of temperature due to the reaction should be avoided in any suitable way, such as by applying cooling during the reaction, at least when employing large quantities and a great strength of acid, a lower temperature being suitable when employing a strong sulfuric acid, and the reaction requiring a longer time when using a dilute acid than with a strong acid. The various conditions as to temperature, time, strength and quantities are therefore mutually dependent on one another, so that it is impossible to give definite limits of general validity for each of these factors. Exact conditions can easily be found out in each special case. The test is very simple: The conditions are properly chosen when the reaction mass dissolves in water and no considerable amount of insoluble, resinlike products separates out. Instead of formaldehyde itself, bodies which give rise to formaldehyde can be used, and instead of sulfuric acid, substituted sulfuric acids can be employed.

These new compounds are characterized by being light-colored amorphous substances containing organically bound sulfur. They are soluble in water, giving rise to almost colorless solutions which assume a red to blue color on the addition of a solution of ferric salt. They are capable of tanning hides and, like the usual tanning agents, do not completely permeate hides unmersed in the solutions within two hours.

The new compounds are probably diphenyl-methane derivatives. On treatment in a cold aqueous and slightly alkaline solution with a small quantity of alcoholic tetrachloroquinone, a coloring matter is formed.

The general method of preparation is illustrated by the following example:

Mix 4 kilos of phenol, or of cresol, with 4 kilos of concentrated sulfuric acid and heat the mixture for some time at from 100° to 120° C. The rise of temperature upon adding the phenol, or the cresol, to the sulfuric acid is usually sufficient to bring about the desired combination. The sulfonated mixture is cooled and treated with 900 cubic centimeters of 40% formaldehyde solution. Run this in slowly and cool the mixture to avoid any considerable rise of temperature. When the reaction is over, the product obtained is an almost colorless, viscous mass which is soluble in cold water. The solution can be employed directly as a tanning vat. Before use the reaction product can be treated with alkali, such as caustic soda, or soda, but it is not advisable to neutralize the mixture completely, or to make it alkaline.

Manufacture of Derivatives of Toluene, Chlorinated in the Side-Chain

Dr. H. D. Gibbs and George A. Geiger of the Bureau of Chemistry, Department of Agriculture, Washington, have recently devised a method for producing the various derivatives of toluene chlorinated in the side-chain, which promises to be of some importance in the dyestuff industry (Amer. Pat. 1,246.739, of Nov. 13, 1917).

The patent is dedicated to the public and can be used in the United States by any one without payment of royalty.

Heretofore various methods have been employed for the production of derivatives of toluene containing chlorine substituted in the side chain, among which are the following:

1. By passing chlorine into boiling toluene in the presence of light until a certain weight of the chlorine is absorbed, a mixture of the different chlorine compounds is produced. The principal products are those in which the chlorine is substituted in the side chain

but there are also present compounds containing chlorine in the ring.

2. On mixing gaseous toluene in excess and chlorine gas in the presence of light and a catalyst, only a portion of the toluene is attacked with the production of benzyl chloride. The latter is mixed with unattacked toluene and the catalyst and must be subjected to a purification process, which adds to the expense of the process.

3. By mixing gaseous toluene with an excess of chlorine gas in the presence of a catalyst a mixture of benzyl chloride, benzal chloride, benzotrichloride, chlortoluene, chlor-benzyl chloride, etc., is produced. This action is somewhat analogous to (1), above mentioned, due to the fact that the reaction takes place in successive stages and the yield of any one desired product can not be exactly controlled.

It is now found that when toluene, converted into the gaseous state, is mixed with chlorine gas in certain definite theoretical proportions in the presence of ultra violet rays, the desired products are produced in greatly increased yields and without the production of unfavorable, undesirable and interfering by-products.

For example:

1. When streams of gaseous chlorine and gaseous toluene are mixed in proportions agreeing with the following reaction:

$$C_6H_5CH_3+Cl_2=C_6H_5CH_2Cl+HCl$$

the principal product obtained is benzyl chloride.

2. When streams of gaseous chlorine and gaseous toluene are mixed in proportions agreeing with the following reaction:

$$C_6H_5CH_3+2Cl_2=C_6HCHCl_2+2HCl$$

the principal product obtained is benzal chloride (benzylidene chloride).

3. When streams of gaseous chlorine and gaseous toluene are mixed in proportions agreeing with the following reactions:

$$C_6H_5CH_3+3Cl_2=C_6H_5CCl_3+3HCl$$

the principal product obtained is benzotrichloride.

It has been found possible to approach these ideal conditions by carefully regulating the speed at which the gases are simultaneously introduced into the reaction chamber.

Moreover, it is advisable to work without the presence of a catalyst. It is not essential to the reaction and contaminates the product, thus adding to the expense of the process.

It is thus apparent that the invention introduces a decided improvement inasmuch as it is possible to produce certain particular derivatives of toluene containing chlorine in the side-chain without the presence of large quantities of other derivatives containing more or less chlorine.

The procedure for making benzyl chloride is as follows:

The reaction chamber consisting of material, resistant to all substances taking part in or produced by the reaction, is swept clear of air by the introduction of an inert gas, such as carbon dioxide. This reaction chamber is provided with a lamp such as the quartz mercury lamp, which emits ultra violet rays. The liquid toluene is then fed by means of a pump at the rate of 60 grams per minute into a vaporize heated by a resistance coil which converts it into the gaseous condition. The vapor is then led from the vaporizer into the reaction chamber. The chlorine is delivered from the cylinder, or electrolytic cell, through a measuring apparatus directly into the reaction chamber through a tube concentric with that of the toluene tube at the rate of 46 grams per minute. The product of the reaction collects on the bottom of the chamber and is drawn off at suitable intervals without the introduction of air. The hydrochloric acid formed is led off through the top of the chamber and absorbed in water.

For making benzal chloride or benzotrichloride the features outlined above are the same except that the rates of delivery of toluene and chlorine are different. To produce benzal chloride the toluene is delivered at a rate of 60 grams per minute and the chlorine at 92.5 grams per minute. For benzotrichloride the rates are, toluene 60 grams per minute, chlorine 139 grams per minute.

A Method for Condensing Salicylic Acid Vapor

It is common practice to volatilize salicylic acid at a temperature of between 130° C. and 160° C. with the aid of superheated steam to convey the acid vapour to the condenser. In a recent patent (Br. Pat. 106,616 of 1916), R. J. Pugh, of the London Chemical Works, Southall, Middlesex, describes a new process for the condensation of the vapor of volatilised salicylic acid from a mixture of that vapor with steam.

According to this method, salicylic acid vapor is condensed and separated from the steam by passing the mixture into a condensing chamber, part or whole of whose wall is pierced by capillary interstices through which the steam is transmitted so that condensation of the acid and its separation from the steam occur within the chamber, and more or less simultaneously. A convenient material for the wall is woollen canvas, but a variety of other materials are available, provided they are chemically free of iron and unattacked by salicylic acid vapor. Such a material will become saturated with condensed steam, and will then provide on its inner face a condensing surface on which further steam will condense, and on its outer face a surface from which water will evaporate, so that a continuous transfer of water will take place through the saturated material by condensation on the inner face and simultaneuos evaporation on the outer. It is thus the water which is the real vehicle for the transfer, while the

Texas Sulphur Company.

Plans are being made by the recently organized Texas Sulphur Company, Orange, Texas, to install the oven system of extracting sulphur as used in Sicily for countries. The company was chartered with a capital of $500,000. A. C. Fleig is president and A. C. McFarlane is vice-president.

Recovery of Light Oils

(*Concluded from page 376*)

This liquid passes upward through a tank containing a solution of caustic soda. By this process any sulphonated olefines which remain in the toluol are removed. Otherwise they would be broken up in the column still and have a destructive action on the dephlegmator and condenser. The condenser coil and connections of this intermediate still should be made of lead.

The final distillates are considered as substantially pure materials if their specific gravities also agree with those which have been determined for the pure constituents. If, however, the specific gravity is lower than that of the pure benzol or toluol it is indication of the presence of paraffins, and to a certain extent the lowering is a measure of the amount of paraffins present.

It is understood that there is no commerically feasible way of separating these paraffins; and in the case of toluol, if the amount exceeds two per cent. the toluol is unfit for the manufacture of explosives. It is stated by some operators that by regulating the speed of distillation it is sometimes possible to make the paraffins distil into other than the toluol fraction, even when present in excess in the crude toluol; but the real remedy is to adjust the gas-making conditions so that the paraffins will not be produced. It is evident that special knowledge and skill are necessary from beginning to end of the recovery process.

Organic Symbols

(*Concluded on page 378*)

the direction of the clock-hand movement when the compound is *LEVO*-rotatory, and in the reverse direction when the compound is *DEXTRO*-rotatory. In inactive compounds the direction of the tails will balance: Compare e.g. dextro, levo-lactic-acid, dextro-levo-glycericacid in *Figure 2* and d- and l-leucine in *Figure* 5.

(b) in *HETEROCYCLIC* compounds a dot outside the lines indicate the heterocyclic atom (either O, N or S) thus differentiating better homocyclic from heterocyclic compounds.

Tautomeric forms, which express themselves mainly in a different arrangement of the double bonds, are very clearly indicated by the symbols and an arrow pointing both ways indicates the equilibrium. Thus compare e.g Phloroglucin and uric acid in *Figure* 5.

Trans- and cis-types of compounds are illustrated in *Figure 2* by maleic and fumaric acid.

The field of organic chemistry is so vast that it is difficult to select a few cases, but I hope that with the help of the figures the idea of *ORGANIC SYMBOLS* is conveyed sufficiently to recognize the importance of such a system.

Berkeley, July 1, 1918.

Ultra Violet Light

(*Concluded from page 386*)

below the lines which they accompany. There appears to be no connection between the mechanisms which produce the D-lines and the visible channeled spectra on the one hand and the ultra violet double lines on the other. The evidence seems to show that the different lines of the Balmer series and their accompanying channeled spectra are produced by different entities, and it is suggested that these are atoms which have lost one, two, three, four, etc., electrons. *Bevan* (Phil. Mag., 1910 (iv), 19, 195) has found that the principal series lines of potassium appear in much greater numbers in the absorption spectrum of potassium vapor than in any form of emission spectrum which has yet been examined. The method of experiment consisted in heating potassium in a steel tube, the ends of which were closed by quartz plates. A beam of light was passed through the tube, and the emergent beam was examined by means of a quartz spectrograph.

Salicylic Acid Vapor

(*Concluded from page 388*)

canvas or other substance serves as a support for the water.

An advantage arising from the method is that the resulting crystals, being condensed in a chamber entirely free of all traces of iron or other metals which in the ordinary water-cooled metal condensers are likely to contaminate and spoil them, are free of all such impurities. Further, the crystals thus produced are comparatively dry owing to the escape of the steam through the walls of the condenser, and to the retention of any condensed steam in the canvas walls crystals obtained are so dry as to contain only 1 per cent of moisture, and consequently not requiring any further treatment beyond the application of very gentle heat, thus preserving the natural crystalline formation, and avoiding further risk of contamination.

Chemical Plant Near Completion.

Work will soon be completed on the new addition to the plant of the Valley Chemical Co., La Salle, Ill. Production will probably be started within the next three months.

Pyrotol Chemical Co.

Chemical and kindred products will be manufactured by the recently incorporated Pyrotol Chemical Co., Beaumont, Texas. The capital of the new concern is $35,000 and the incorporators are, Bruce Richardson, S. Gordon, E. J. Goodier and A. H. Safir.

"Indefilco" Presses Office Comes Home.

The Independent Filter Press Co., Inc., announces the removal of their office from 47 W. 34th St., New York City, to 418 Third Ave., Brooklyn, N. Y. This move is expected to speed up production, as factories and office will now be under one roof. A. Couttrell will supervise the manufacturing end of the business.

Foreign Trade Opportunities

Further information can be obtained by addressing the U. S. Bureau of Foreign and Domestic Commerce, Washington, D. C. Write each application on separate sheet.

Oleomargarin

26599.—An agency is desired by a man in Switzerland for the sale of lards, butter, *oleomargarin and substitutes*, and allied products; also rosin. Correspondence may be in English. Reference.

Chemical Products

27047.—A man in France desires to purchase *chemical products* and drugs. Quotations may be made f. o. b. New York. Payment will be made against documents. Correspondence should be in French Reference.

Paints, Colors and Matches

27069.—A man in the United States who is representing a firm in England desires to purchase and secure an agency for the sale of piece goods, hardware, iron products, all kinds of machinery, *paints, colors, matches*, buttons and laces. References.

Chemical Products

26593.—A man in Spain desires to secure an agency for the sale of general merchandise, including *chemical* and pharmaceutical *products*. Correspondence should be in Spanish. References.

Tanning and Dyeing Materials

27109.—An agency is desired by a man in Italy for the sale of medicines, drugs, *tannery and dye materials*, colonial goods, and oil seeds. Catalogues, samples, and price lists should be submitted. Correspondence may be in English. Reference.

Metals and Chemicals

27044.—The American representatives of a firm in Norway desire to secure an agency for the sale of foodstuffs, *chemicals, metals*, raw materials, and general merchandise of every description. Quotations should be made f. o. b. New York. Payment will be made against shipping documents and established credit in New York.

Caustic Soda Crystals

26920.—A man in Venezuela desires to receive cable quotations on 300 drums of 350 kilos each of *crystallized caustic soda*, 78 per cent grade. The price should be made f. o. b. New York delivery. Payment will be made in New York against shipping documents.

Various Leathers

26914.—A firm in Switzerland desires to purchase all kinds of *leathers*, such as waxed and flexible splits, glaced kids, hemlock and oak sole leather, harness leather, and saddlery, and motor-car leathers. Quotations should be made f. o. b. Boston or New York.

Masek Co. Adds to Plant.

The contract has been awarded by the Masek Glue Co., 908 Denison Ave., Cleveland, Ohio, for the erection of a one-story 30x60 foot glue factory. The cost is estimated at $40,000.

American Ingraft Co.

With a capital of $25,000 the American Ingraft Co., Inc., has been incorporated under the laws of New York to manufacture chemicals, etc. The principal incorporator named is Morris Yedlin.

To Manufacture Paper.

Paper and paper products will be manufactured by the firm of S. Walter, Inc., Philadelphia, Pa., which was recently incorporated with a capital of $75,000. Harry Lefkowitz is the principal incorporator.

Pyodine Chemical Co.

With a capital of $25,000 the Pyodine Chemical Co. has been incorporated at Los Angeles, Cal., to manufacture chemicals, etc. The incorporators are Dr. David Osterhold, E. Osterhold and Fred B. Osterhold.

HELP WANTED

PRACTICAL EXPERT wanted in manufacture of food products; one knows how get results from raw materials; give experience, reference, etc. C., c/o Chemical Engineer.

MECHANICAL AND CHEMICAL ENGINEER—A manufacturer wants a man with above qualifications to help develop his present method of production; state detail experience, age, and salary expected. Write Engineer, Room 611, World Building, New York City.

WANTED, ANALYTICAL CHEMIST FOR FERTILIZER FACTORY. A fine opportunity for an energetic and ambitious young chemist understanding machinery and with knowledge of heat engineering and practical chemistry. Write "V. C.," c/o Chemical Engineer.

WANTED—Chemist; female, analytical and research. Apply during business hours, or phone Ossining 1057 for an interview. Ossining Chemical Works, Ossining, N. Y.

WANTED—Organic Chemist, of high caliber; must have had experience in research, plant design and plant operation, a man of character and ambition required, who can qualify for responsible position in growing organization within thirty miles of New York City. Initial salary up to five thousand, depending on qualifications. State nationality and necessary details, which will be held in strict confidence. Box J. C., c/o Chemical Engineer.

CHEMIST for position as factory manager; must have thorough training in chemical engineering; draft exempt; best of references required; good salary with excellent chances for advancement. Apply Mangano Manufacturing Co., 17 Seminary Ave., Rahway, N. J.

Will Mine for Phosphates.

The Armour Fertilizer Works, Chicago, are planning the erection of a $150,000 plant for the mining of phosphates near Columbia, Tenn.

NEW PUBLICATIONS

Copper

A new publication issued by the U. S. Bureau of Standards, Circular No. 73, is entitled "Copper."

This circular deals primarily with the physical properties of pure and of commercial grades of copper. The best data and values are given for the various physical characteristics and constants, together with a bibliography of the sources from which these values were taken. The effect of impurities upon the properties of copper is dicussed as well as the influence of various factors in its manufacture, and altogether the circular should be of great interest to every one concerned with the production of this metal, and altogether the circular should be of great interest to everyone concerned with the production of this metal.

This paper is now ready for distribution and those interested may obtain a copy by addressing a request to the Bureau.

Photoelectric Sensitivity of Bismuthinite

A new publication of the Bureau of Standards, Scientific Paper 322, is entitled "The Photoelectric Sensitivity of Bismuthinite and Various Other Substances."

This paper summarizes the results of an investigation of various substances (1) for an increase in electrical conductivity caused by the action of light upon them, and (2) for photoelectrical activity when they were charged to a negative potential, in an evacuated chamber and exposed to light.

Of the various substances examined, none were found which are as sensitive to light as the selenium cell, and the potassium photoelectric cell.

Experiments are described in which some of these substances are used as photophones.

This paper is now ready for distribution and those interested may obtain a free copy by addressing a request to the Bureau.

Thermal Expansion of Alpha and of Beta Brass

A new publication of the Bureau of Standards. Scientific Paper No. 321, is entitled "Thermal Expansion of Alpha and of Beta Brass."

The Bureau has been investigating, recently, the failure of brass articles, rods, bolts, etc., by crack-

BECKMANNS
THERMOMETERS

Gottwik, Scheffer & Co.
25 Church Street, NEW YORK
HYDROMETERS
CALORIMETER

ing. Instances have been observed in which cracking occurred in brass articles which had been quickly cooled from a forging or annealing temperature by quenching or otherwise, and it was considered possible that this may have been due to the development of local stresses in the brass during such cooling. The present study was made with a view to ascertaining the approximate magnitude of the local stresses which might be set up in heterogeneous brasses of the type Muntz metal, and the effect of such stresses upon the mechanical properties of this metal.

This paper is ready for distribution and those interested may obtain a free copy by addressing a request to the Bureau.

"Effect of the Size of Grog in Fire-Clay Bodies"

A new publication of the Bureau of Standards, Technologic paper 104, is entitled "Effect of the Size of Grog in Fire-Clay Bodies."

The size of grain has long been known to exert considerable influence upon the properties of mortars, concrete, fire clay refractories, and other materials. The present investigation determines the effect of the size of the calcined portion, or grog, upon the properties of fire clay bodies within a field of practical sizes. The general plan of procedure consisted of separating grog into a number of sizes, recombining these in arbitrary proportions by calculation from triaxial diagrams, mixing with an equal weight of clay, and molding with water into test pieces for raw state, as indicated by the modulus of rupture, depended upon a number of factors and did not vary directly with the size of grog. Proper proportions of grog sizes gave stronger bodies than single grog sizes. The strength of burned bodies increased directly with decrease of the size of grog, the size being expressed numerically as a surface factor. Bodies containing the large sizes were more resistent to sudden heating and cooling from 600° C. and 1000° C. Volume shrinkage in burning to cone 12 increased approxi-

OCTOBER, 1918

IF there was anyone who, after a visit to the Fourth Chemical Exposition in the Grand Central Palace during the week of September 23, was still disinclined to question the time-honored fable of Germany's pre-eminence in the field of industrial chemistry, a reading of either the speech of the president of the British Chemical Society, published elsewhere in this issue, or of the article published in a recent number of the *Economic World*, entitled "The Myth of Germany's Pre-Eminence in Chemistry," should effect a cure. In both cases it is clearly shown that, first of all, the coal tar color industry owes its origin to British chemists, that very few of the useful elements were discovered by Germans, and furthermore that, although until the beginning of the war, Germany had made more of the coal tar color industry than any other nation, since the outbreak of the war, American chemists and manufacturers have made greater progress in the production of dyes than Germany ever did in the same period.

So far as the mineral chemical industries are concerned America, even before the war, could stand comparison with Germany or any other country. In fact, when it comes to the production of acids and heavy chemicals, we are, in many branches, decidedly ahead of the Teutons.

THE regrettable disaster at the Gillespie shell loading plant in New Jersey has again drawn public attention most forcibly to the dangers that exist in war time for those even three thousand miles away from the front line trenches. While no cause has been yet assigned by those investigating the explosion, it is to be hoped that both the investigators and the public in considering the placing of responsibility will remember the wise words of Dr. W. G. Hudson, medical director of the Dupont Company, in a recent paper entitled "Safeguards in the Manufacture of Explosives," "If explosives like dynamite, smokeless powder and TNT were made only by skilled chemists under the best of laboratory conditions, they would seldom, if ever, cause explosion accidents. . . . But when these substances are produced in the immense quantities required by present conditions, ordinary labor must be used, and many of these men are unskilled and have no speaking knowledge of English. However careful our chemists, supervisors and foremen may be, it is difficult to guard against someone of these thousands becoming careless at times and, of course, the results of an explosion are visited upon all in the vicinity."

IN the light of the present fuel shortage, the recent meeting of the American Peat Society was of particular interest. Several scientists of note, pointed out in the course of the meeting ways and means whereby the nation's peat bogs could be made immediately available.

While it is hardly likely that in the midst of war anything will be done either in the United States or elsewhere to make the world's immense peat resources of use to industry, it can, however, be safely predicted that with the close of the war the attention of chemists in all parts of the world will be directed towards the very important problem of making peat available as a competitor of coal. The successful solution of this problem, bringing as it will, immense fields within the reach of not only industry, but the private consumer as well, will solve many a sociological and manufacturing problem. It will perhaps eliminate to a certain extent one very prolific cause of war—the international controversies over the possession of coal fields.

In Great Britain a great deal of experimentation has already been done and considerable success has been experienced in making an easily handled and very marketable peat fuel. The success met with by the English chemists and scientists is no doubt an indication of what may be done in the not far distant future by other nations.

The decision of the Advisory Committee of the National Exposition of Chemical Industries, to hold the next Exposition in Chicago, cannot help but stimulate public interest in the chemical industries of the Mid-West.

Chemical Show Proves Year's Progress

Exhibits at Fourth Annual Chemical Exposition Give Clear Indication of Great Strides Made by American Industrial Chemistry During Past Year—Attendance Greater Than Ever Before.

AMERICA had another answer to fling back at Germany during the week of September 23rd. This time the answer came from the chemists of the United States and was delivered in the form of the Fourth National Exposition of Chemical Industries at Grand Central Palace, in New York, which, literally interpreted, declared that America has, within the short period of several years, freed itself from the predominance of German chemistry. The imperative war time needs of this country for chemicals that, previous to 1914, we were solely dependent upon Germany for providing, have been met as a result of the activities of our own chemists and scientists. This the recent exposition at New York very strikingly demonstrated.

In all respects the Fourth National Exposition of Chemical Industries was a success far beyond the most sanguine expectations of those interested in its promotion. It graphically illustrated the marked strides that the American chemist has made during the past few years; it showed the generous and unselfish co-operation that the chemist as an individual and the chemical industry in its entirety have extended to the Government in the promotion of its war activities. The record-breaking attendance that marked the exposition proved the closer relationship that now exists between the American public and the American chemist. The display also brought into contact the banker, the manufacturer, the business men and the chemist.

The New York display was truly a war-time exposition of America's chemical and chemical manufacturing achievements in furthering the Government's war making activities. For this reason the exposition probably exceeded in importance, and in its broad relation to the nation's welfare, any similar industrial exposition held in the world, due to the fact that chemistry, in a greater or less degree, enters into every industry and is playing a deciding part in gas warfare.

Practically every branch of chemistry and allied lines was represented, the exhibits covering, among others, dyestuff manufacture, the by-products of coal and coke and iron and cement, pharmaceutical chemistry and apparatus, biological chemistry, and machinery ranging from the simplest appliance to a complete plant for intricate processes; copper and other metals, aniline products, enamels, synthetic dyes and colors, corks, asphalt, lenses, foundry products, engineering apparatus, porcelains, etc.

During the last year great strides have been made in the industries based on chemistry. Among the latest achievements the country is now producing potash from several sources, and as a by-product in the manufacture of iron and cement. It has developed and improved the manufacture of light metals for airplanes, heavy metals for every purpose, dyes, soda and bleaching powder, lenses, special pottery, excessive heat-resisting utensils, etc.

The Government Exhibits

The Governments of Canada and the United States were represented at the show, the Canadian Government presenting the materials it has available for development by the chemists and the financiers. The United States Government, through its Gas Offense Division, had an interesting exhibit of incendiary bombs, gas shells and gas bombs. After viewing this exhibit one had a full realization of what the chemists have accomplished in perfecting methods of offense and defense in gas warfare.

"For display that ordinarily would be considered solely as a scientific show, the attendance was truly remarkable," stated Dr. C. H. Herty, chairman of the Exposition Advisory Committee, at the close of the exposition. "It emphasized one outstanding feature, that the war has created a keener interest on the part of the general public in the development of war necessities and the part that chemistry plays in their production. Likewise, it has created a closer relationship between the American public and the chemist. As an educational display the exposition ranked high, for even the most

casual visitor in the Palace could obtain a liberal education by a survey of the exhibits. To many business men the exposition provided an opportunity to discover some methods of utilizing or profitably disposing of some by-product of their business which heretofore had been discarded. It brought all trades and professions together for the interchange of ideas. Generally speaking, it was a huge success."

Coal Conservation Illustrated

A new angle to the Garfield fuel conservation orders was provided by an immense display board showing samples of the various products derived from coal. To the average person coal is considered simply in the light of fuel, but a study of the display board at the Palace disclosed the fact that no less than 212 products are derived from this mineral. These products range from the heavy coal tar to the light liquid perfumes and paints.

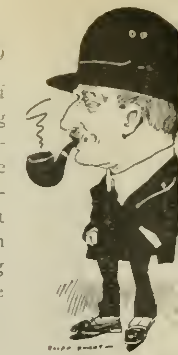
The Chemical Exposition afforded a most striking demonstration to the advanced position of the American chemical industry in answering the dye and drug situation. Scarcely two years have elapsed since many lines of our industrial life were threatened with utter demoralization because of the shortage of dyestuffs and medicinals resulting from the blockade of German ports by the British navy. Textile mills faced imminent possibilities of shutting down because of the inability to secure dyestuffs for the fabrics. Tanners, lithographers and wall paper men sought in vain for needed coloring matter, and pharmacists' stocks of many much-needed medicinals became depleted. On account of these shortages and the accompanying speculation in the remaining stocks, prices soared to undreamed of heights.

F. F. UEHLING, Of the Uehling Instrument Company, "hits it up" occasionally along the country roads.

The exposition showed that within this short period of two years, one of which had been devoted to war preparations, a miracle has been wrought. All lines of industrial life which formerly depended upon imports are now operating under normal conditions, and in addition we are now shipping large quantities of these former imported products to foreign countries.

The Development of Ceramics

America's development of its ceramic industries during the past few years to the position where the United States is now absolutely independent of Germany and Austria for supplies of its firebrick, pottery, glass, etc., was clearly shown at the Chemical Exposition. The ceramic branch of the chemical industry is daily gaining in importance. At the beginning of the war but little optical glass was being manufactured in this country. The necessity of the war brought together the manufacturers and scientific and technical organizations with the result that the developments in this field have been truly remarkable. The most interesting advancements in the glass industry have been those relating to the optical, colored (signal) and the resistant or chemical glasses, which heretofore were produced chiefly by Germany.



DR. W. LEINER
Of the Leinert E
neering Co., was ca
by the artist loo
over his exhibit

The Chemical Exposition was a growing illustration of the advantage to our industries which chemistry has afforded. The growth of our industries of all kinds has been greatly assisted by chemists. Strictly speaking, all industries are chemical industries, but some industries are more obviously chemical industries than others. This exposition had to do naturally more with the industries which are obviously chemical, but the general proposition that all industries are dependent upon chemical processes should be emphasized, even if, in each case, the connection is not obvious to the unthinking man. This war has taught us that all industry is more or less chemical in its character.

Industry Doing Its Part

What the great chemical industry in this country is doing to produce the big Allied victory, what America has accomplished in taking the enormous chemical, glass and dye industries away from Germany—and taking them permanently—was demonstrated most decisively at the Exposition. Most potent were the wonderful ramifications of this basic industry demonstrated. While no high explosives or poison gas was exhibited, owing to their dangerous nature, the processes by which they are obtained and manufactured was illustrated by machinery exhibits, large and small, and by motion pictures. Naturally, the side of chemistry which is related to munitions was most interesting to the general public. Gas masks and their operation, bombs, high explosive shells, etc., loomed importantly in the layman's mind, but equally important were the wonderful new industrial chemical and electrochemical processes and inventions operated on a most gigantic scale since the United States went to war—operated on a scale never even conceived in peace times.

Next Show in Chicago

In conjunction with the exposition the annual conventions of several chemical and technical organizations were held. These conventions brought many chemical engineers and experts to New York City for the first time since the present great development of the chemical business in this war as a result of the cutting off of imports of chemicals and dyestuffs from Germany and other foreign countries since the beginning of the war.

Thousands of Chemists Visit Grand Central Palace

An immense number of out of town visitors inspected the various exhibits during the week. Not the least interested from out of town points were C. H. Kimberly, of Philadelphia; P. H. Walsh, of the Dominion Textile Company, of Montreal, Canada; Dr. Richard Moldenke, of Watching, N. J.; Dr. C. G. Derrick and Dr. W. H. Watkins, of Buffalo, members of the National Aniline and Chemical Co.'s Buffalo staff, and Dr. C. K. S. Mees, of the Eastman Kodak Co., Rochester.

Instead of conducting groups of Pratt Institute students around the Exposition, as in former years, this time Major Rogers was kept busy behind the booth of the Chemical Warfare Service to which the sometime professor has been attached since May.

E. Haefel, chief of the laboratories of the Robert Gair Company, Brooklyn, in spite of the fact that he is a very busy man these days, managed to spend a few hours during the week looking over the exhibits, and meeting the many friends from all parts of the country, he found at the Exposition.

R. L. Vilas, assistant sales manager of the Dupont Chemical Works, was in charge of the Dupont Company's fine exhibit.

Not all of Mr. Vilas many friends in the industry know that in addition to being an engineer of sales of no small ability, he is a member of the American Society of Magicians, of which Harry Houdini, the "handcuff king" is president.

Dr. Arthur D. Little, of Arthur D. Little Inc., spent several days at the Exposition, presiding over the potash symposium Wednesday afternoon.

Dr. W. R. Whitney, research director of the General Electric Company and a member of the Naval Consulting Board, visited the Exposition during the week and spent a number of very profitable hours visiting the various exhibits.

A certain contemporary described Corporal Charles F. Roth, of the Chemical Warfare Service, one of the joint managers of the Exposition, as a "modest, gentle-spoken soul." Some of those who have encountered the corporal in his energetic moods would, perhaps, be inclined to question this characterization.

A great number of the men most prominent in the ceramics industry of the United States visited the Exposition during the week. L. E. Barringer, chairman of the special committee of the American Ceramic Society appointed to arrange the meeting of the society held during the course of the Exposition, led the van.

A number of very much interested visitors from overseas dropped into the Grand Central Palace during the course of the Exposition. Major J. H. Brightman, British attache of the Chemical Warfare Service, made a very thorough-going tour of the Palace during the week and expressed himself as being very much interested.

Dr. Bernard C. Hesse, of the General Chemical Company, a man who has taken a leading part in the revision of the available American chemical statistics, was a frequent visitor to the Exposition during the week.

Ensign D. Delahanty, who is now engaged in doing airplane research work as a member of the personnel of the naval air service, at Rockaway Naval Air Station, visited the booth of the Chemical Engineer early in the week.

Many Interesting Exhibits at Show

A tour of the exhibits in the Grand Central Palace during the Fourth Chemical Exposition was a liberal education to either the layman or the more sophisticated technical man; the layman came to see that chemistry and its allied processes played a larger part in the body industrial than he had ever thought, and the technical man was able to discover what his brother chemists had succeeded in doing during the year just past.

In its old place on the ground floor the exhibit of the Buffalo Foundry and Machine Company, in point of dignity and impressiveness probably exceeded most of the other exhibits at the Exposition. The central feature of this exhibit was a gigantic 5,000-gallon nitrator, which, by the courtesy of a customer, the company was permitted to show at the exposition. Such is the demand for the company's products, that all the chemical apparatus shown were taken from the company's experimental laboratories. The exhibit was in charge of E. G. Rippel, the sales manager of the Buffalo Foundry and Machine Company.

A veritable romance of chemistry was epitomised in the Dupont exhibit to the north of the entrance on the ground floor. The wealth of industrial materials derived from coal tar bases was visualized for the visitor to the Exposition in a most illuminating and interesting way. After looking at this exhibit the visitor came to the conclusion that having contributed materially towards the demolition of the German war lords the Dupont Company was now preparing to demolish the German commercial barons. In making this exhibit of their dyestuff products the Dupont Company sought to emphasize the importance of the corporation's achievement in erecting in the space of ten short months a plant capable of turning out enough synthetic indigo to supply the total needs of the United States.

In these days when coal conservation is one of the big problems of the day among manufacturers, the booth of the Uehling Instrument Company, featuring the firm's coal economizing devices, attracted a great many visitors. Those in charge of the booth said that the company had all it could do these days keeping up with its orders.

The wide range of apparatus for the conduct of chemical warfare in its various phases, exhibited on the second floor, by the Chemical Warfare Service of the United States Army under the direction of Major E. F. Briethut, until recently a professor at the College of the City of New York, was throughout the exposition the centre of attention. Gas masks, gas shells and grenades of various nations were shown and both chemist and non-technical men were enabled to appreciate to some extent the part the chemist was playing in the actual fighting of Uncle Sam's battles.

Speaking of dyestuffs, the exhibit of the National Aniline and Chemical Company, featured the company's two latest achievements: The production of two fast colors for which the textile trade has been waiting, Alizarene Sapphire and Carbanthrene Blue. Alizarine Sapphire is the fastest known level acid dye to light for wool and Carbanthrene Blue a vat dye of the greatest fastness to washing for cotton.

There were a whole series of bull's eyes on the products exhibited by the New Jersey Zinc Company, indicating that the company has been fighting the Huns in its own way. There was a bull's eye on their drawn zinc rod and wire and another on zinc oxide U. S. P., now being made for the first time in this country in large quantities.

Industries Grow Under War's Stimulus

Representatives of Chemical Industries and Allied Enterprises Emphasize Great Progress Made by All Branches, in Speeches Delivered at Conferences Held During Chemical Exposition.

During the course of the conferences held on the third floor of the Grand Central Palace during exposition week a great many papers were read and speeches delivered dealing with various aspects of the development of the chemical industries of the United States since the outbreak of war in 1914. Taken as a whole these messages from chemists in all parts of the country, interested in half a dozen different branches of industrial chemistry, enabled those fortunate enough to attend the conferences to appreciate to some extent not only the problems the chemists of the country faced in 1914, but enabled them to appreciate the gigantic proportions of the industries at the present time. For the benefit of those who were prevented from attending all or any of these conferences the following abstracts of some of the papers read are printed.

C. KINGSBURY,
ngineer of the Gen-
amics Co., “looking
natural.”

That there has been a nine hundred per cent. increase in the manufacture of nitric acid in the United States since the war began in 1914, was the statement made by E. L. Pranke, in the course of a paper read before the conference held on the afternoon of the 24th. Incidental to this vast increase in the volume of acid manufactured, there had been an equally great increase in the efficiency of the manufacturing methods, an increase which was typified according to the writer by the introduction of such improvements as the substitution of modern fire boxes provided with proper “arch” for the Dutch ovens, the replacing of the chemical stoneware from the retorts to the condensers, and the glass condenser tubes by acid-proof, high-silica iron, and the replacing of the ordinary form of rings in the towers by the spiral ring.

In 1914, 78,589 tons of nitric acid of ordinary strength had been produced, according to the census of the manufacturers and 112,124 tons of mixed acids. According to other data given in the census these figures represented about 89,000 tons of 100 per cent nitric acid. All of this acid had been produced from nitrate of soda consuming about 160,000 tons of nitrate. The pre-war importation of nitrate amounted to about 560,000 tons of nitrate per annum, hence the normal consumption of nitrate for other purposes than the manufacture of nitric acid was about 400,000 tons.

The present rate of importation, the writer said, was about 1,600,000 tons of nitrate per annum. Mr. Pranke estimated that about 1,000,000 tons of nitrate is now being converted into nitric acid. This was equivalent to 650,000 tons of 100 per cent. nitric acid of which nearly five-sixth is being used for the manufacture of military explosives.

Yet greater developments were predicted for the future by Mr. Pranke. The nitric producing rate in the spring of 1919 would be about 650,000 tons from nitrate of soda and about 225,000 tons by oxidation of ammonia from the air, a total of 475,000 tons of 100 per cent. nitric acid or about nine times the pre-war normal consumption.

While Mr. Pranke predicted further development of the nitric acid manufacturing industry he warned those present at the conference that with the coming of peace, over four-fifths of the acid producing capacity will have to be shut off from the decrease in demand.

Touching upon the improvements that had been made in acid making plants since the beginning of the war, Mr. Pranke said that important changes in equipment and operation, such as the increasing of the charge of nitrate from 5,000 to 7,500 pounds per retort, the operation of the retorts in rotation instead of in batches as formerly, and the substitution of two for three runs a day per retort, had resulted in a decided increase in the amount of nitrogen recovered as acid from an average of about 78 to 80 per cent. to about 92 to 94 per cent. of the nitrogen in the nitrate of soda.

So far as the development of new methods was concerned since the outbreak of the war in 1914, Mr. Pranke emphasized the great strides made by the ammonia oxidation industry. He felt that the successful development of the ammonia oxidation process justified to a certain extent the belief that it would be the principal source of nitric acid in the future. The differential between ammonia gas and sulphate of ammonia would make a difference in favor of ammonia oxidation of from 15 to 20 per cent.

Utilization of Sawdust.

George H. Tomlinson, of Niagara Falls, Canada, in a paper dealing with the utilization of wood waste as a source of ethyl alcohol, said that if the millions of tons of wood waste annually produced in the United States were to be made use of, in the production of alcohol, a radical change must be made in the methods used by those who are seeking to develop the industry.

There were a number of reasons why, in Mr. Tomlinson's opinion the industry centering about the manufacture of ethyl alcohol from wood waste had not developed as rapidly as its possibilities justified. The industry, he believed had been injured to a great extent by the fact that many of the promoters of companies, formed to engage in the manufacture of alcohol from wood waste, had been more interested in the formation of the companies than they had in the development of the industry itself. Adequate research had not in many cases preceded the location and the building of the plants, and plants had been located and built in many cases without due consideration having been given to the commercial conditions involved.

It had been originally assumed, the speaker said, that every sawmill represented a possible location for the establishment of an ethyl alcohol plant. It was further assumed that since there were innumerable sawmills where the disposition of sawdust was a serious problem, that this material could be bought in large quantities at a merely nominal figure. In making these assumptions the early promoters of the industry had overlooked the fact that although there were undoubtedly immense quantities of sawdust turned out by the mills in all parts of the country, there were few at which the conditions were entirely favorable for the establishment of the extensive plant which the manufacture of ethyl alcohol requires. They forgot also that there were a number of other factors, beside the supply of raw material, to be taken into consideration, such as the water supply, the labor supply and the question of transportation.

Electrochemistry and War

The important part the electrochemist has played in assisting the Administration in its war work was emphasized by F. J. Tone, president of the American Electrochemical Society, in an address made during the afternoon of the opening day of the Exposition.

The chemical industry of the United States has made great strides during the past four years, Mr. Tone said, and no small part of this advance had been due to the part played by electrochemistry in the industrial processes of the country.

"America has long enjoyed a supremacy in electrochemistry, but in spite of the strong position of the industry before the war no one would have dared to predict the expansion which the war would demand of us," said Mr. Tone in the course of his speech. "It has called for chlorine, cynamide, air nitrates and phosphorus in vast quantities. It has required the ferro alloy industry, the electrode industry and the abrasive industry to quadruple their outputs."

While the electrochemical industry as a whole had nobly met the demands made upon it by the nation's war needs, it was imperative Mr. Tone insisted that they remember that their war work is only begun. If this war was a chemists' war, the peace that would come after it would be a chemists' peace. When peace came no one would have a better opportunity to serve his fellow man than the chemist. For with them rested the solution of the problems involved in the conservation and proper utilization of our resources, the elimination of wastes, the problems of foodstuffs, clothing and sanitation.

Making of Pyrophoric Alloys

The manufacture of pyrophoric-alloys or "sparking metals" from the by-products of the Welsbach gas mantle manufacturing industry was described in detail by Dr. Alcan Hirsch, in a paper entitled, "The American Pyrophoric Alloys Industry," during the afternoon of the 27th.

Most of the thoria used in the manufacture of Welsbach mantles was now derived from monazite sand, Dr. Hirsch said. In the United States about a quarter of a million pounds of throium oxide was annually produced from over five million pounds of monazite sand. The by-products of this process contained more than a million pounds of the "cerium oxides" annually. These oxides constitute the raw material of the American pyrophoric alloy industry.

The cerium metals are reduced in an electric furnace by electrolyzing their molten salts. The metal so obtained after being alloyed with about thirty per cent. of other metals, is formed into small "flints" to be used in lighters, igniters, mechanical fuses and other similar devices.

The Chemist and Industry

"The general proposition that all industry is more or less dependent upon chemistry should be emphasized, even if the connection in each case is not obvious to the unthinking man," said G. W. Thompson, president of the American Institute of Chemical Engineers, at the conference held on the opening day of the exposition. "We learn by adversity. This war has taught us that all industry is more or less chemical in its character . . . and we, seeing the extent to which chemistry could be of service to the nation, have learned a lesson, although our education in this direction is not complete."

Mr. Thompson appealed to those who controlled manufacturing processes to learn more fully the need of chemical knowledge for the perfection of industry. In addition the speaker said that the colleges and universities must learn that however valuable pure chemistry might be as a study or as a means of mental discipline the most important thing that chemistry does is in its application. Chemists, too, he said, must learn more fully and completely the need of applying their knowledge to chemical processes conducted on a large scale.

"Manufacturers," continued Mr. Thompson, "can do a great deal to help the universities and colleges in developing more efficient methods of instruction. They can do this by calling university and college professors into their councils and developing the practical side of these professors so that the students will be developed along lines which will be useful to industry.

"Practical business men often distrust college professors. They say that they are theoretical and visionary. This in many cases is due to the fact that the practical business man has a narrow vision. Sometimes it may be true that the instructors in chemistry have not a practical turn of mind. Whether this view of business men is true or not the remedy lies in their own hands, and if they will see their broad duty they will throw open their plants more freely to instructors in chemistry and make the education of chemists a part of their organized plan. In other ways our colleges and universities must be used by our manufacturers, and our manufacturing plants must be opened to use by our universities and colleges."

"To assure the industries of the United States permanent chemical independence," said Dr. Charles H. Herty, chairman of the Advisory Committee, in formally declaring the exposition open on the afternoon of the 23d, "there must be brought about the closest possible cooperation."

(Continued on page 432)

Shawinigan Hopes to Rival Niagara District

Granting of Big Contract for Acid to Canadian Electrochemical Company Draws Attention to Developments and Future of Industries Located in Northern Quebec.

By J. HERBERT HODGINS,
Manager Statistical Department, Union Bank of Canada, New York City.

THE recent announcement that the Shawinigan Water and Power Company, of Shawinigan Falls, Quebec, Canada, had been given the contract to erect and operate a plant for the manufacture of acetic acid for the United States Government, has served to indicate in a most emphatic way to American chemists and manufacturers a changing balance of power in the American electrochemical industries, a changing alignment of forces presaged for some time past by the questioning of the supremacy of the Niagara Falls district as the centre of the electrochemical industries of the continent. This impression was rendered more emphatic by the statement made incidental to the announcement of the granting of the contract, that the step had been taken because, in the opinion of the authorities at Washington, the Shawinigan Water and Power Company was the only corporation on the continent possessing immediately available power resources to undertake the manufacture of acetic acid in large quantities.

While the fact that the United States Government was willing to send the necessary funds to Canada to finance the enterprise was in itself significant of the relations existing between the United States and her northern neighbor, the fact possesses peculiar interest to those Americans, either chemists or manufacturers, interested in the development and future of the electrochemical industries of the continent.

This official recognition on the part of the United States Government of the claim made by the American capitalists, backers of the Shawinigan enterprises, indicates that those enterprises and industries centering about Shawinigan Falls represent the premier water power enterprise of the continent. This being the case, it is fairly safe to say that American capital, when aiming to locate and develop electrochemical industries, must continue to consider to an even greater extent than heretofore the vast resources possessed by her northern neighbor in accessible, but as yet, undeveloped water power.

The resources and the stage of development reached in the Shawinigan district should, therefore, prove not only interesting to the capitalist with industries to locate, but should particularly interest the chemist and manufacturer who already connected either directly or indirectly with one or other of the electrochemical industries, seeks to ascertain something of what the future holds for the electrochemical industries of the United States.

The Location of Development

The main developments of the Shawinigan Water and Power Company are located at Shawinigan Falls, midway between Montreal and Quebec City, the town deriving its name from an old Indian word indicating the resemblance between the aboriginal quill and bead work and the great falls of the St. Maurice River, the river where the town of Shawinigan stands.

Until 1898 Shawinigan, now a city of over 12,000 inhabitants, consisted of one house. But with the coming of the engineers of the original Shawinigan Falls Development Co., the formation of the Pittsburg Reduction Company and the building of the Canadian Northern Railway, the history of the city and the industries which rapidly sprang up about the Falls began. In this year the Legislature of the Province of Quebec granted the Shawinigan Water and Power Company a charter, giving it a wide range of power. The Provincial Government also sold the company all the property upon which the city now stands and handed over the water power on the St. Maurice River at this point. Thus the company came into possession of 11,000 acres of land and one of the greatest natural water powers in the world, a falls with a drop of 150 feet.

Falls Have Immense Power

Then came the development of the Falls. A canal or forebay was excavated from a point near the crest of the Falls, about a thousand feet west, the end of the canal being closed by a concrete wall, in which were placed headgates and entrances to penstocks. These penstocks conducted the water from the forebay walls through their length of 450 feet to the power stations at the lower level. This canal has a depth of 20 feet at low water and at its narrowest point has a width of 100 feet. It is capable of developing 150,000 horse power.

The first electric installation consisted of two 5,000 horse power water wheels and generators. Gradually thereafter the plant was enlarged to utilize the capacity of the hydraulic works until the installation in No. 1 station reached the amount of 55,500 horse power.

At Shawinigan Falls the Shawinigan Water and Power Company now has in operation four power houses with a capacity of 196,000 horse power. The latest house of this development has five 20,000 horse power units and nine miles above Shawinigan there is yet another power house with an installed capacity of 120,000 horse power.

Company Keeps Eye on Future

The Shawinigan Company has had an eye to the future as well as the present, and has acquired water rights and other rights preliminary to the possible development of 75,000 horse power at the Gres Falls, four miles below Shawinigan. Here there is a head of 65 feet. In addition to this within one hundred miles there are other undeveloped water powers with a potential capacity of over 300,000 horse power. Totaling the present developed and possible power available, the immediately visible supply of power capable of being fed to the Shawinigan system amounts to 1,091,000 horse power, of which 550,000 is understood to be unsold.

The present developments of the company summarized come to this—there is now installed 511,000 horse power of generating machinery feeding the system. Forty thousand horse power is at present available for prompt delivery. About 580,000 horse power is yet undeveloped and this, with the horse power still unsold, makes 680,000 horse power available for the electrochemical industries located in the St. Maurice valley.

Of the electrochemical industries located in and about Shawinigan, the Northern Aluminum Company, formerly the Pittsburgh Reduction Company, was one of the first to locate on the St. Maurice. American refined bauxite is brought up by rail and reduced to aluminum. This company uses about 60,000 horse power for this purpose. The Northern Aluminum Company has also a wire and cable manufacturing plant and manufactures practically all the aluminum wire made in Canada.

Many Industries at Work

The Canada Carbide Company uses 40,000 horse power in manufacturing calcium carbide and acetylene gas.

The Shawinigan Electro Metals Company, another of the city's industries, produces metallic magnesium in many forms and sells the greater part of its product in Canada.

One of the largest industries in Shawinigan is represented by the plant of the Canadian Electro Products Company, a plant put into operation only since the beginning of the war. This company manufactures acetic acid and acetone from acetylene gas supplied by the Canada Carbide Company.

Another of Shawinigan's industries is the Prest-o-lite Company. This company operates an acetylene gas compressing plant, using gas supplied by the Canada Carbide Company.

The steel industries are represented by the experimental electric furnace plant of the Fraser Brace Company, where various types of steel are manufactured.

The Canadian Aloxite Company, a subsidiary of the Carborundum Company, is building an extensive plant covering about 15 acres and will make use of, it is expected, about 20,000 horse power.

The pulp and paper industry is represented by the plant of the Belgo-Canadian Pulp and Paper Company and the Laurentide Company, which respectively utilize 18,000 and 28,000 horse power.

A further development of the electrochemical industries of the district is represented by the plant of the Canadian Electrode Company. This company, as its name indicates, manufactures electrodes.

Even from such a cursory examination of the present development and the future possibilities of the Shawinigan district of Northern Quebec, it is apparent that the industries already developed and likely to be developed in this district in the near future are destined to play no mean part in the immediate future in the electrochemical industry of the continent.

Japanese Dye Factories

Japanese factories manufacturing dyestuffs now number more than one hundred, exclusive of a great many small ones turning out inferior goods, according to a recent issue of the Japan Advertiser. The same authority claims that the total investment in these hundred factories represents over $7,000,000. In spite, however, of the development of the Japanese dyestuff industry since the beginning of the war in Europe, the domestic market is still said to be dependent for its supplies upon importations from foreign countries A feeling is said to be evident among the more farsighted members of the dyestuff industry in Japan that without proper protection against foreign competition only a comparatively few of their number will be able to survive for any length of time the coming of peace. These men have persuaded the Government to undertake the investigation of proposals whereby a high tariff wall around the Empire to protect the Japanese industry.

The incorporation is announced from Albany of the Zenith Drug & Chemical Company, with an authorized capital of $5,000. The incorporators are W. I. Newman, E. C. Davidson and T. F. Thornton.

R. Pettinger, H. Brach and A. Regan, of 70 Fifth Avenue, Manhattan, are announced as the incorporators of the United States Emergency Ration Company, with an authorized capital of $100,000. The company's charter authorizes it to engage in the manufacture of foodstuffs and chemicals.

German Manufacturers Using New Cellulose Yarn

Reports from Germany Indicate that Under Stress of Raw Material Shortage Hundreds of Mills in Teutonic Countries Are Making Yarns of Wood Pulp.

REPORTS reaching this country from Germany by way of various neutral countries, serve to indicate that under the stress of the shortage of raw materials brought about by the allied blockade, German chemists and manufacturers have met with considerable success in their efforts to evolve a cellulose yarn from wood pulp. While the manufacturers of paper yarn met with little success in their attempts to obtain a suitable substitute for wool and cotton yarns, if all reports may be believed, a greater degree of success has been attained by those who have sought to make fibres derived directly from cellulose.

The progress made by German chemists and manufacturers in manufacturing a yarn from cellulose, out of which durable garments can and are being made, should prove of great interest to American chemists, not so much because of the implication of the fact that the people of Germany have reached such extremities that they are driven from lack of raw materials to seek such methods of clothing themselves, but also because it is not at all unlikely that for many years after the conclusion of peace, wool will be scarce and expensive, and because German manufacturers of textiles are already declaring their intention of manufacturing vast quantities of garments made from mixtures of cellulose fibre and cotton or wool for export to all parts of the world. If only to equip themselves against the effects of this threatened competition, American manufacturers will be compelled to keep in touch with the developments of this new industry which has sprung up in Germany.

That there exists in America an opportunity for an industry of a similar nature, there seems to be little reason to doubt. The manufacture of artificial silk from cellulose and similar materials has reached within the last few days vast dimensions, and there seems to be little reason why with a knowledge of the proper technique, a similar industry could not be built up around the production of fibres from wood pulp.

Writing in the *Frankfurter Zeitung*, the textile labor leader Kratzig, makes the following statement in regard to the process at present being tried out by some of the German textile manufacturers:

"For cellulon, the cellulose fibres are prepared in the same way as for paper manufacture, usually without addition of resin. The material is run over a revolving sieve, where it is cut into strips as the water runs off. These strips are then wound on bobbins and while still moist brought to the spinning machine. The paper yarn thus made is smoother and stronger than that made from strips. After the war paper yarn, no matter how made, will be used only for coarse materials, such as sacking. This new staple fiber is different. It is made after the material has been dissolved into a jelly-like mass. This mass is spun through a fine sieve which delivers very fine fibers. These fibers are spun into threads, which can be dyed any color. This yarn is not now washable, but great efforts are being made to find some method which will make it so. The material can, it is true, be washed but when moist it is weak and soft. It, however, regains its strength when dried. By mixing some cotton with the material, a cloth can be made which can be washed like pure cotton goods. If wool is mixed with it, it makes a fine cloth. This yarn can be woven on any kind of a loom."

The same man writing in the *Konfektionar,* another German publication, reveals the fact, that in spite of the progress made so far with this new fibre, efforts to improve it still further were being retarded at the time of writing by the indifference of the Government and the selfishness of the owners of the patents under which it is manufactured.

"The Government," he says, "should take the initiative to support the experiments for the improvement of this fiber. The textile industries have for months been applying to the Government for help to produce this fiber and nothing has been done. The reason for this inactivity on the part of the Government lies in the difficulties made by the corporation which exploits the patents. . . . If we go about this work systematically and take care that the fiber as well as the material produced from it is not subjected to the same price increases as the paper weaves were we can look forward to the future with confidence. If we make earnest efforts to utilize this fiber in the right way, we have nothing to fear from the economic war. As for the wool

Cross Index of Chemical Terms

Compiled by E. R. Darling.

THIS cross-index was prepared as an aid in finding true chemical names and other synonyms associated with them. Only those chemical compounds whose name does not indicate their true chemical terms are here listed.

Some general titles are:

"Butter" of a metal refers to the Chloride.
"Calcined" of a metal refers to the Oxide.
"Caustic" of a metl refers to the Hydroxide.
"Flowers" of a metal refers to the Oxide.
"Muriate" of a metal refers to the Chloride.
"Vitroliate" of a metal refers to the Sulfate.

Acid Cardonate of Potash—See Potassium Bicarbonate.
Acid Carbonate of Soda—See Sodium Bicarbonate.
Acid Potassium Sulfate—See Potassium Bisulfate.
Acid Potassium Tartrate—See Potassium Bitartrate.
Alabaster—See Calcium Sulfate.
Alum—See Potassium Aluminum Sulfate.
Alumen—See Potassium Aluminum Sulfate.
Alum Flour—See Potassium Aluminum Sulfate.
Alum Meal—See Potassium Aluminum Sulfate.
Alumina—See Aluminum Oxide.
Aluminite—See Potassium Aluminum Sulfate.
Alumini Ustum—See Dried Potassium Aluminum Sulfate.
Amido Chloride of Mercury—See Ammonium Mercuric Chloride.
Ammoniated Mercury—See Ammonium Mercuric Chloride.
Ammonio-Chloride of Mercury—See Ammonium Mercuric Chloride.
Anglisite—See Lead Sulfate.
Anhydride of Antimony—See Antimony Trioxide.
Anhydrous Arsenic Acid—See Arsenic Oxide.
Anhydrous Arsenious Acid—Arsenious Oxide.
Anhydrous Arsenicosm—See Arenious Oxide.
Anhydrous Calcium Sulfate—See Dried Calcium Sulfate.
Anhydrous Chromic Acid—See Chromic Trioxide.
Antimony Black—See Antimony Sulfide.
Antimony Bloom—See Antimony Trioxide.
Antimony Grauce—See Antimony Trisulfide.
Antimony Red—See Antimony Pentasulfide.
Antimony Vermilion—See Antimony Trisulfide.
Antichlor—See Sodium Thiosulfate.
Aqua Calcis—See Calcium Hydroxide
Aragonite—See Calcium Carbonate.
Arsenic—See Arsenious Oxide.
Arsenic Anhydride—See Arsenic Oxide.
Arsenic Blanc—See Arsenious Oxide.
Arsenic Orange—See Arsenic Trisulfide.
Arsenic Yellow—See Arsenic Trisulfide.
Arsenious Acid—See Arsenious Oxide.
Arsenious Anhydride—See Arsenious Oxide.
Asbolite—See Cobalt Oxide.

Barite—See Barium Sulfate.
Baryta—See Barium Oxide.
Barytes—See Barium Oxide.
Badic Carbonate of Magnesium—See Magnesium Carbonate.
Bichloride of Mercury—See Mercuric Chloride.
Bihydrate of Lime—See Dried Calcium Sulfate.
Biniodide of Mercury—See Mercuric Iodide.
Binoxide of Lead—See Lead Dioxide.
Binoxide of Manganese—See Manganese Dioxide.
Bismuth Yellow—See Bismuth Trioxide.
Bismuth White—See Basic Bismuth Nitrate.
Bismutite—See Basic Bismuth Carbonate.
Bitter Salts—See Potassium Chloride, also Magnesium Sulfate.
Blanc Fixe—See Barium Sulfate.
Black Lead—See Lead Dioxide.
Black Oxide of Cobalt—See Cobalt Oxide.
Black Oxide of Copper—See Cupric Oxide.
Bleaching Powder—See Calcium Hypochlorite.
Black Mercury—See Ammonium Mercurous Chloride.
Black Precipitate—See Ammonium Mercurous Chloride.
Black Oxide of Mercury—See Mercuric Oxide.
Blue Coppras—See Copper Sulfate.
Blue Salts—See Nickel Sulfate.
Blue Stone—See Copper Sulfate.
Blue Vitriol—See Copper Sulfate.
Bone Ash—See Calcium Phosfate.
Bone Earth—See Calcium Phosfate.
Brilliant Scarlet—See Mercuric Iodide.
Brown Acetate—See Calcium Acetate.
Brown Lead Oxide—See Lead Oxide.
Butter of Antimony—See Antimony Chloride.
Butter of Arsenic—See Arsenic Chloride.
Butter of Cadmium—See Cadmium Chloride.
Butter of Chrome—See Chromium Chloride.
Butter of Cobalt—See Cobalt Chloride.
Butter of Silver—See Silver Chloride.
Butter of iZnc—See Zinc Chloride.
Burnt Alum—See Dried Potassium Aluminum Sulfate.
Burnt Lime—See Calcium Oxide.

Cadmium Yellow—See Cadmium Sulfide.
Cake Alum—See Aluminum Sulfate.
Calcite—See Calcium Carbonate.
Calcined Gypsum—See Dried Calcium Sulfate.
Calcined Magnesium—See Megnesium Oxide.
Calcined Mercury—See Mercuric Oxide.
Calcined Plaster—See Dried Calcium Sulfate.
Calomel—See Mercurous Chloride.
Calomelas—See Mercurous Chloride.
Calx Chloride—See Calcium Hypochlorite.
Calx Chlorinata—See Calcium Hypochlorite.
Calx Chlorate—See Calcium Hypochlorite.

Artificial Silk Chemists' Triumph

Industry's Central Chemical Problem of To-day Is to Produce Fiber Possessing Even Greater Tensile Strength and Pliability—Industry Has Interesting History.

By LEONARD KEENE HIRSHBERG, A.B., M.A., M.D.

ACCORDING to Mr. C. Ainsworth Mitchell, the manufacture of the products known as "artificial silk" affords a striking instance of a successful superficial imitation of a natural substance.

The idea of producing by mechanical means fine fibres which would possess the luster and other characteristics of silk and be strong enough to be woven into fabrics is by no means new, although it is only within the last twenty years or so that any degree of commercial success has rewarded the attempts made in this direction.

As far back as 1734 it was suggested by the French naturalist Reamur that since silk was to be regarded as a naturally hardened "gum" it might be possible to produce similar lustrous fibres by forcing some varnish, such as that used by the Chinese, through minute openings, and drying the filaments thus obtained. But this idea was not followed up and it was not until after the lapse of a hundred and twenty years that any practical attempts to produce such artificial fibres appear to have been made.

In 1855 a patent was taken out in England by Andemais for the manufacture of fine threads from cellulose. The fibres from the bark of mulberry trees were converted into an inflammable compound and dissolved in a mixture of alcohol and ether, as in the early "wet plate" process in photography, and the solution mixed with a solution of indiarubber. A steel point was dipped in the viscous solution and the threads adhering to it when removed were drawn out as finely as possible by means of a winding machine and left to dry.

The Mechanical Problem Involved.

The invention may be regarded as the parent of many of the successful processes of the present day, most of which are based upon dissolving cellulose or its compounds in some suitable solvent, and passing the solution through fine openings so as to form filaments which remain in a flexible form on removal of the solvent by evaporation or otherwise. The problem which has been more or less satisfactorily solved in these processes is, in the main, a mechanical rather than a chemical one, for it is not owing to any difference in chemical composition but to a difference in physical structure that silk possesses a lustre which ordinary cotton lacks.

There are in fact, numerous vegetable fibres which resemble cotton in chemical composition but have a silken lustre owing to their possessing a surface like that of silk. Thus the seed hairs of the plane Eriodendeon anfractinosum closely resemble silk in appearance, and certain varieties of cotton have fibres of such a form that they are much more lustrous than the more common kinds. This difference is so pronounced that long before the invention of artificial silk, seed cotton was sometimes used as a silk substitute, its natural lustre being increased by singeing off the fine hairs upon the surface or by rolling.

Making Vegetable Fibres Silky.

Simple treatment with certain chemical agents is also sufficient to alter the surface of certain non-lustrous fibres in such a way that they reflect the light, or in other words, become lustrous. A familiar example of this is seen in the mercerization of cotton in which under the combined influence of caustic alkali and of tension the characteristic flattened twisted fibres become straightened into more or less cylindrical tubes having a high degree of lustre. In like manner a silken lustre may be imparted to jute fibre by immersing it for a short time in a strong solution of caustic soda, and then washing it with soda.

But in such cases as these there is only an alteration in existing fibres, which still remain much coarser than those of natural silk, whereas in the artificial products the fibres are constructed from the beginning and in some of the best preparations are but slightly thicker than those of genuine silk.

This stage of excellence has taken long to reach, mainly owing to the mechanical difficulties of producing fibres of such fineness. After the publication of the Andemais patent nothing further was heard of the production of an "artificial silk" until 1883, in which year Mr. J. W. Swan patented a method of obtaining threads from a solution of nitro-cellulose in acetic acid or other solvent, forced through small openings and subsequently rendered non-explosive by treatment with ammonium sulphide or other deoxidizing agent. These fibres were intended primarily for use in the manufacture of mantles for incandescent gas-burners, but are described in the patent as "artificial silk," and were used experimentally in the weaving of textiles.

The Beginning of the Industry.

Two years later Count Chardannet took out his first patent, the chemical principle of which was similar to that of Swan's patent, and this may be regarded as the beginning of the industry.

In Chardannet's process cotton or wood pulp is converted into nitro-cellulose, which is dissolved under pressure in a mixture of alcohol and ether so as to yield a viscous solution. This is conducted through pipes into a series of troughs in the spinning room, each trough ending in a small glass jet 1/100 millimetre in diameter. The filaments forced through these "silk-worms," as they are called, were formerly delivered under water, but better results are now obtained by a process of dry spinning, in which the solvent is made to evaporate. Four, six or more filaments are spun together, and the threads pass through ammonium sulphide solution to denitrate them, with the result that they are rendered non-explosive and even less inflammable than ordinary spun cotton. Finally the silk is dyed to any color required.

The methods of du Vivcei and of Libner in 1889 are very similar to the Chardannet process. In the former the nitrocellulose is dissolved in glacial acetic acid and the solution mixed with solutions of gutta percha in carbon bisulphide and fish glue in acetic acid, before being passed through the minute orifices; while in the latter the nitro-cellulose solution is incorporated with a solution of silk waste, and the fine filaments precipitated by means of water.

Many Other Solvents Used.

Cellulose rendered soluble by other means than nitration has also been employed in the manufacture of artificial silk or "lustra-cellulose," as it has been more appropriately termed. Thus in some of the methods of cellulose in an ammoniacal solution of copper oxide is employed, in others the cellulose is dissolved in zinc chloride solution, and in others again, a solution of the compound of carbon bisulphide with alkali-cellulose is used. But the principle underlying them all is the same, that is, the formation of fine filaments of the viscous cellulose solution and subsequent separation of the solvent.

The "Vandenara silk," patented in 1894 by Mr. A. Millon of Glasgow, is the first example of another class of artificial silk, and as regards its chemical composition approximates more closely than the "lustra-cellulose" to the natural product. It is prepared by forcing a concentrated solution of gelatin through small openings on to a rapidly moving endless band, which draws the threads out into fine filaments. These are twisted together and exposed to an atmosphere of formaldehyde vapor, which speedily renders them insoluble in water, and leaves them lustrous and supple. The threads spun from the filaments may be dyed readily any desired color, and are absolutely inflammable, but they have the drawback of being greatly inferior to silk in strength, and this defect becomes more pronounced when they are moistened with water.

Moistening Reduces Strength.

When moistened with water the strength of the silk is little if at all affected, whereas the strength of the lustra-celluloses is reduced to about one-eighth, although on drying they regain their original strength. This drawback of deficient strength is shared by all the artificial silks, though the lustra-celluloses are superior in this respect to gelatine "silk," and all are quite as strong if not stronger than genuine silk that has been "weighted" by the addition of metallic compounds, as is now frequently done. Although quite as lustrous as silk, some of the artificial products have a scintillating appearance which the genuine substance lacks, and all feel harsher to the touch.

With the exception of gelatin "silks," which do not seem to have been extensively employed, artificial silks are readily distinguishable from silk or wool by the fact that they burn without emitting the characteristic smell of burning animal nitrogenous matter.

They may also be distinguished by their appearance under the microscope, especially in transverse section, in which they usually appear as irregular shapes, generally considerably larger than the regular pointed ovals of the transverse sections of ordinary silk.

Various chemical agents may also be employed for their detection and differentiation. Thus a solution of copper oxide in ammonia dissolves both the natural and artificial silks, but on the addition of water the cellulose composing the latter is reprecipitated, whereas no precipitate is obtained from the solution of silk. Again, the Chardannet silk may be differentiated from the viscose silks by the fact that in the case of the former faint traces of nitro-cellulose remain, however carefully the denitiation is carried out. These may be detected by giving a bright blue coloration when the "silk" is treated with a solution of diphen-glamine in strong sulphuric acid.

Their deficiency in strength has prevented artificial silks being used more extensively for clothing, but they are largely employed in the manufacture of ribbons, and for tapestries upholstery and other decorative work in which strength is not a primary consideration, and owing to their relatively low price and beautiful lustre are well suited for such purposes.

Tariff Commission Chemist Sees Bright Future

Grinnell Jones, Chemist to the United States Tariff Commission, Reviews Development of American Chemical Industries Before American Chemical Society and Forecasts Their Possible Future.

WHEN peace is restored the competitive strength of the nations in all industries will have been profoundly altered. Chemistry and machinery have played a larger part in this war than in any previous war, and therefore the greatest changes may be expected in the metal working and in the chemical industries. Moreover, our new American cargo ships will make us more than ever interested in foreign trade. The Tariff Commission is actively studying these war disturbances in order to assist in the readjustment and reconstruction that must follow when peace comes.

Among the chemical industries, the first to feel the stimulus of war was the explosive industry. The expansion of American smokeless powder plants was sufficient to prevent a German victory in France and Russia in 1915. It is not revealing military secrets to say that there has been some growth since 1915. We all hope that the peace terms will be so satisfactory that the military explosive plants themselves will no longer be needed. Nevertheless, there will be a permanent increase in the competitive strength of the American chemical industries through the growth of the subsidiary industries which now supply the raw materials to the explosive industry.

Increase in Acid Making.

Our production of sulphuric acid is at least twice what it was before the war. The growth has been largely in contact acid, and therefore when the demand for explosives disappears, the American chemical industries will have available large supplies of pure and concentrated sulphuric acid. Moreover, the growth of the acid industry has been made possible by a great increase in the production of American sulphur and by a smaller although signification increase in the mining of pyrites.

The nitric acid industry has grown relatively more than the sulphuric acid industry. The output of nitric acid from Chilean niter is now more than ten times as great as it was before the war.

The significance of this growth of the sulphuric and the nitric acid industries to our dynamite, dyestuff and pyroxylin plastic industries need not be emphasized here.

Of greater significance than this stimulus to industries already well established has been the birth of new industries. We have a new synthetic ammonia and nitric acid industry. Plants have been built and, during the war at least, will be operated by the Government. When the full story of these plants can be told, it will reveal that American chemists have, under the pressure of war needs, been able to devise substantial improvements upon the Haber and Ostwald processes developed by the Germans before the war. These processes were the result of nearly two decades of work on these problems as a part of their military preparedness. It is not improbable that after the war nitric acid made from synthetic ammonia may prove to be cheaper than nitric acid made from Chilean niter. In any case American agriculture will assuredly have a new large source of nitrogenous fertilizer materials.

Oil Production Grows

In 1914 our production of crude light oil would have been sufficient for the production of only about 4,500,000 gallons of benzol and of about 1,500,000 gallons of toluol, and only a part of which was distilled. As is shown in our forthcoming report on the production of American dyes and coal tar chemicals, in 1917 our putput of benzol was 40,200,000 gallons, and of toluol, was 10,200,000 gallons. In 1918 further substantial growth is to be expected through the installation of stripping plants at city gas works. The toluol is now going almost entirely into explosives as is also a considerable fraction of the benzol. When the demand for explosives disappears, it is to be expected that the prices of benzol and toluol will drop to the point where it will be profitable to add them to gasoline for motor fuel. A similar condition will probably exist abroad, and, since America has the greatest known natural resources for the production of gasoline, benzol and toluol should be as cheap or cheaper here than abroad. Therefore the industries consuming benzol and toluol may be assured of ample supplies of these materials at favorable prices.

The Future for Phenol.

Before the war we had no synthetic phenol industry, whereas in 1917, as is shown in our forthcoming report, 15 plants produced 64,146,499 pounds of phenol valued at $23,715,805, most of which was used in making picric acid. If this new industry is to survive, there must be a greater consumption of

(*Continued from page* 419.)

phenol in the industries for peaceful purposes. Fortunately, phenol is used as an intermediate in the manufacture of some representatives of every class of finished coal-tar chemical products, including dyes and lakes, photographic developers, medicinals, flavors, perfume materials, synthetic rosins, synthetic tanning materials and explosives. Leaders in the chemical industries are already making plans for the industrial development of the uses of phenol when the phenol is no longer needed for explosives.

Another war-baby is monochlerbenzol, which was made during 1917 by eight American firms, with an output of nearly twenty-five million pounds, valued at a little less than five million dollars. The dye industry will use a part of this productive capacity permanently, but new discoveries by American chemists will probably be needed to utilize the total productive capacity. Incidentally, this product furnishes a new outlet for chlorine, a new by-product source of muriatic acid, and raises a new problem in the utilization of dichlor-benzol, an unavoidable by-product.

An Industry Built to Last.

Before the war there was but one producer of anilin oil in the United States. In 1917 there were twenty-three producers with an output of 28,806,524 pounds, valued at $6,758,535. As only a relatively small proportion of this substance goes into explosives, the peace readjustments will not be complicated by a collapse of a military demand, but will depend primarily on the competitive strength of the American industry.

The war has also stimulated the production of mercury for the manufacture of fulminates. The American production has about doubled since the beginning of the war. Formerly we had a balance of imports—now we have a larger balance of exports.

Poison gas warfare is also destined to have a permanent influence in the chemical industries. Although there is no reason to expect that uses will be found for phosgene and mustard gas on a scale approaching the present and prospective military use, the plants erected for their manufacture need not prove a total loss when the military demand ceases. Nearly all of the noxious substances used in poison gas warfare require chlorine for their manufacture, and an increase in the production of chlorine in the United States is therefore certain. There is much hope that some of the substances produced as intermediate steps in the manufacture of the poison gases may be utilized for purposes other than warfare, but these are matters not yet to be discussed. Phosgene, except for the dangers attending its use, is an excellent reagent for many processes involving chlorination or dehydration and for making Eichler's ketone. Fortunately, the risk in using phosgene is greatly minimized by the development of the new gas mask. The intensive work which hundreds of American chemists have been and are doing to improve the design of the gas mask will undoubtedly prove a blessing to workmen exposed to noxious fumes in chemical factories throughout the world when peace is restored.

War's Effect on Acetone.

Still another industry which has been stimulated by a direct war demand, is the manufacture of acetone, which is used as a gelatinizing agent in the manufacture of the explosive, cordite; as a solvent for airplane dopes; and in the manufacture of poison gases. Before the war acetone was obtained entirely as one of the products of the wood distillation industry, but there are now at least four new processes in commercial operation in the United States or Canada for the manufacture of acetone.

It has been found that glucose can be fermented by a suitable organism to give acetone directly. Butyl alcohol, is a by-product of this fermentation, and becomes commercially available in appreciable amounts. The development of uses for butyl alcohol is an attractive problem.

The other processes for making acetone produce acetic acid or an acetate as an intermediate step, and may therefore permanently affect the acetic acid industry. The most obvious and perhaps the simplest of these processes depends on fermenting molasses to alcohol, which is then converted into acetic acid by the rapid vinegar process. The conversion of acetic acid into acetone is an old and well-known process, but the details have been improved.

Another process depends on making acetylene from calcium carbide. By the aid of a suitable catalyst, the acetylene is made to combine with water yielding acetaldehyde which may be readily oxidized to acetic acid. Still another process depends on fermenting kelp under such conditions that sodium acetate and potassium salts are secured.

Dyestuff Industry's Future.

The war has stimulated the production of many other products, a few of which may be briefly mentioned; castor oil for lubricating airplane motors; phosphorus for incendiary bombs; barium and strontium nitrates for signal rockets. The output of soda ash has increased by 68 per cent. since 1914, and the output of caustic soda has more than doubled.

New conditions in the chemical industries have also been created by the curtailment of imports. As a direct consequence of this stoppage of imports from Germany a new American dye industry has been established. It is true that some dyes were being made in the United States before the war, but the makers relied on Germany for the necessary intermediates, with the exception of a small amount of anilin made here by a single producer. During

Time for Changed Educational Policy

Prof. William Jackson Pope, C.B.E., D.Sc., F.R.S., Tells Members of British Chemical Society That Hereafter Education Must Be More Scientific and Practical—War Has Discredited So-Called "Classical" Education.

COMING from the president of the most important body of chemists of Great Britain, and containing, as it therefore does, the gist of the lessons learned by that country as the result of over four years of war, the following speech, delivered by Prof. William Jackson Pope, president of the Society of Chemists of Great Britain, should prove particularly illuminating to those interested in the promotion of scientific education in the United States. It contains a number of lessons which American educators would do well to study and put into practice:—

For three years past pure chemical research has been dormant the whole world over, and it would be difficult fo rthe most accomplished essayist to arrest your attention for an hour by an address on a subject of purely academic interest. Our mental point of view and our outlook upon both present and future are entirely different from those of four years ago; although the present is obscure and painful, the future gives promise of brilliant and rapid developments in natural science in general and in chemistry in particular. In this belief I venture to lay before you some reflections upon the growing recognition of importance of our science and upon the responsibilities with which, owing to this change in public opinion, our shoulders are laden.

Anyone who is in the habit of reading modern historical writers—and they have become quite illuminating since a scientific mode of writing history has been substituted for the older fictional style—knows how political changes, national reforms arising from an effort of the collective conscience, the magnetic influence of some popular demagogue, and the like, are invariably invoked as explanatory of all the vicissitudes of our planet.

The modern historian is here taking a false point of view, and, since he is, in general, quite unacquainted with physical science, his methods are inadequate. The whole history of Europe for the last century has been made within a few hundred yards of Burlington House in our scientific laboratories. One of the most potent incentives to political changes resides in the desire to increase the amenities of life, and research in pure science has had for a hundred years past the greatest influence in facilitating the realization of that desire. trations of the stultifying effect of a purely classical education are laid before us every day; one recent example may be quoted here. The gentleman who shares with Mr. A. J. Balfour the honor of representing in Parliament the greatest centre of business and financial activity in the world made the following statement in the House of Commons recently whilst opposing Mr. Fisher's Education Bill: "It was said that education was necessary to make the rising generation good business men. His experience in the city was that the man who took Firsts at Oxford generally came out last, and that ehe man who could hardly write his name generally came out first. The explanation was that education could not put into a man that instinct of self-preservation and common sense which was the foundation of all sucess in business. How could education assist a farm laborer to spread manure on a field. The best laborer he had known was wholly illiterate. If the waste of the war was to be replaced it would be necessary for the young men to start as early as possible in doing a day's work, instead of wasting time on useless book learning." This representative of the city of London is a baront of recent creation and a director of one of the largest London banks and of one of the most important railroads; he received his "education" at one of the oldest and most rigidly classical of our great public schools. Comment is probably unnecesary.

Science and Literature

Every scientific man in the world realizes that an innate appreciation for fine literature, for great thoughst nobly expressed, and for the appropriate delineation of our greatest aspirations, are among the most sublime instincts of humanity and demand the most careful cultivation. Our literary men say that we cannot express ourselves effectively, and offer as a satisfying feast the old bones left us by the Greeks and Latins, chewed over for centuries until so devoid of nutriment that they led ultimately to the mental atrophy which characterized the Middle Ages, an atrophy that was only shaken off by the taste for calknowledge which arose from the exploits of geographical science in the Elizabethan period.

If the power of expression rests with our literary friends, why are they so idle? It is their obvious duty to devote themselves to popularizing the natural knowledge acquired by the scientific observers of the past two centuries; this real learning has so infinitely extended human interest in the world around us and gives such promise of further conquests that an appeal for its consideration would certainly not have been made in vain to Plato or Lucretius. No one asks for the abolition of classical literary learning, but the whole world is now demanding that the young should be provided with an education which includes an insight into our present-day knowledge of the universe.

The rather petty disputes which rage about this matter of classical and scientific education are one-sided; the scientific man generally knows something of both aspects of the subject, whilst his classical compeer rarely has any acquaintance with science. Unfortunately, the great questions involved have more than a petty bearing upon the well-being of our nation. The classical school has held the country in such bondage that, to all practical intent, no person can be admitted to the higher public service unless he swear adhesion to the caste. It is almost regarded as a platitude that acquaintance with natural science disables a man from fulfilling any high public office; practically all the superior positions in the Civil and Diplomatic Services must be filed by men of classical instincts.

Experience Has Discredited Method.

I venture to think that the wisdom of this mode of selection has been seriously impugned during the last four years. The huge Government departments which classes—those staffed by men of some scientific training and those staffed by classical university graduates. have arisen of late many be divided roughly into two Anyone who has had occasion to note the numerous recent criticisms on Government departments must have observed that these strictures have almost invariably ben passed on administrative branches of the service; delay, the encumbrance of red-tape, and inability to draw a decision, seem indigenious in certain Government offices, and none of the numerous attempts at reform has been successful. The adiministrative services are those in which thec lassical man is predominant. Other branches, such as the home Army Medical Service, have practically never been charged with inefficiency; the worst that has been alleged is a suggestion of extravagance.

The department just named is staffed by men who have had, at least, the rudiments of a scientific education; if control in the Royal Army Medical Service had been vested in the classical scholar of ability but no knowledge, it is certain that the last three years would have seen a repetition of the horrors of the Crimean campaign, and that the army mortality from disease would have been greater than that caused by the ordinary instruments of war.

Such a control, happily, has been avoided; it has been avoided merely because medicine possesses the collective organization for which I plead in chemistry, an organization so strong as to make the imposition of an irresponsible lay control unthinkable.

I have already directed attention to the frequently expressed opinion that, as a nation, we are incapable of excelling in the fine organic chemical industry; let me quote one instance, small in itself, but large in its consequences, in disproof of this view.

The ordinary photographic plate is sensitive only to a region in the blue of the spectrum, but by incorporating certain rather fugitive organic dyes with the sensitive film, the later may be rendered sensitive to the green, yellow, and red parts of the spectrum; photographic plates so treated are described as panchromatic. The quantities of the sensitizing dyes required for the whole world's consumption in normal times is minute, being, indeed, of the order of a few pounds per annum. Until 1915 these substances had never been made outside Central Europe, and little was known by us of their compositions or of the methods of preparing them, as they were all sold under trade names. The manufacture of these materials, small as was the business, had been industriously cultivated by the German color works, and, as these color sensitizers are essential in aerial photography, their scarcity became of serious import quite early in the war.

What Chemists Have Done.

The experimental investigation of the whole subject was quickly put in hand in this country, and within a few months ample supplies of the usual sensitizers were produced. Further, the newly established Department of Scientific and Industrial Research financed the development of the study of photographic sensitizers; as a result of this action new sensitizing dyes have been produced which are far superior to the older ones. It is safe to assert that the manufacture of panchromatic plates has now attained a degree of perfection in this country such as will long defy competition.

This is but one case that may be quoted from among a host of others, all of which prove conclusively that, given a little encouragement and assistance, British chemistry is capable, not only of giving much needed relief in this time of strain, but of meeting every demand which can be made on it when thep eriod of reconstruction comences.

Whilst the absence of the powerful weapon provided by a collective chemical Council, embracing all interests of the science, has made it impossible for us to render the most economical service to our country, it is perhaps satisfactory to reflect that hitherto all that has been sacrificed is economy. Our lact of power to enforce our views has led to financial extravagance on the part of the authorities; the lack of economy in time, which means lives, cannot be attributed to our chemists. The duty will fall to some future President at some later time to record the spontaneity with which the Fellows of this Society volunteered for service in our chemical works, our munition factories, and with the Colors either in our gas service or elsewhere.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS*

Part XVIII

Resonance Spectra.

According to *Wood* (Phil. Mag., 1908, (vi), 15, 581) sodium vapor heated to about 400°, in an exhausted steel tube, shows an extremely complex absorption spectrum consisting of a multitude of very fine absorption lines; the very large scale photographs taken show, for example, about 6,000 lines in the bluish green. If the vapor is illuminated with white light, it becomes fluorescent and gives an emission spectrum which is the exact counterpart of the absorption spectrum. By exciting the vapor monochromatic light, only a few lines appear in the emission spectrum. These spectra are called "resonance spectra," because they appear to be due to resonance of an electron of the system when nonchromatic radiation plays upon it. Only light of certain wave-lengths can excite the resonance spectra, for example, the line 5,209 is the ony one in the spectrum of the silver arc which is active. The electron theory indicates that a non-radiating system of electrons, when disturbed by absorption of radiation of the same frequency as that of one of the electrons, should emit radiations giving a system of equally spaced lines.

Mercury, Cadmium and Zinc.

McLennan and *Edwards* (Phil. Mag., 1915, (iv), *30*, 695) note that the ultra violet absorption spectra of the non-luminous vapors of mercury, cadimum, and zinc, show strong symmetrically spaced bands and narrow, sharply defined bands. In addition, the mercury spectrum shows a diffuse, complex band, for which there are no analogues in the cadmium and zinc spectra.

Absorption by Halogen Salts.

Retchinsky (Ann. Physik, 1913, (iv), 42, 1680; J. Chem. Coc., 1914, *Abs.*, 106, ii, 83) has examined the ultra violet absorption of lithium chloride, lithium bromide, sodium chloride, sodium bromide, sodium iodide, and potassium iodide in aqueous solutions of varying concentration. All these salts show a strong absorption maximum in the extreme ultra violet beyond λ = 220 μμ. The absorption curve is shifted towards greater wave-lengths when the temperature is raised to 100° in the case of sodium chloride, lithium bromide, sodium bromide and potassium iodide, but no shift is observed with lithium chloride. When the limiting absorption of the dissolved salts is compared with that found for the molten salts it is found that the straight lines which represent the influence of temperature in the case of the molten salts pass through the points which correspond with the limiting absorption in aqueous solution at 20° and 100.° *Houston* (Proc. Roy. Soc. Edin. 1912, *32*, 40; J. Chem. Soc. 1912, Abs., *102*, ii, 507) examined the absorption spectra of various salts of copper, silver, lithium, sodium, potassium, rubidium, and caesium and found the absorption in the ultra violet to be very small except in the case of the nitrates. *Massol* and *Faucon* (Compt. rend., 1914, 159, 174; J. Chem. Soc. 1914, Abs., *106*, ii, 694) find that copper nitrate falls into line with other metallic nitrates in giving the ultra violet absorption band of nitric acid, providing that a sufficient thickness of solution is used. The band is, however, less sharply defined, an aqueous solution of copper nitrate being more transparent to the rays between λ 3150 and 2800 than solutions of the other nitrates.

Drossbach (Ber. 1902, 35, 91) in determining how far certain substances (mostly in 10 per cent. solution) absorb the ultra violet rays found a marked absorption in the case of some salts of heavy metals, nitrates, and organic substances with high molecular weight. Hydrochloric acid, sulphuric acid, potassium chloride, chlorate and sulphate, sodium and calcium chlorides, aluminum and manganese, sulphates were found to be transparent, that is, light up to 230 μμ passed through these as easily as through water.

·*Retschinsky* (Ann. Physik. 1908, (iv), 27, 100) has made an examination of the absorption spectra of some thirty molten inorganic salts, the result of which shows that, in all cases, there is a well-defined limit to the absorption band on the ultra violet side of spectrum, all radiation of smaller wave-length than that corresponding with the limiting value being completely absorbed. With rise of temperature this limit is displaced in the direction of greater wave-lengths.

Mercury Salts.

In a study of the light absorption of some metallic salts on the nature of the linking, *Ley* and *Fisher* (Zeitsch. anorg. Chem. 1913, 82, 329) state that the ultra violet absorption of mercuric salts is displaced towards longer wave-lengths in passing from the chloride to the iodide, the bromide being exactly intermediate. Mercuric cyanide is almost as diactinic as water, and much more so than mercuric ions, a result which is explained by the presence of a mercury-carbon linking. In acordance with this, mercuric methyl chloride and mercuric ethyl chloride absorb less than mercuric chloride. On the other hand, compounds with mercury linked to nitrogen, such as mercury propionamide and mercury succinimide, have a high absorption. Mercuric perchlorate absorbs more than the mercuric salt favoring the view that a bivalent complexion $(Hg\,.\,Hg)^{\cdot\cdot}$ is present.

Other Inorganic Compounds.

The behavior of alcoholic solutions of copper, cobalt, and nickel salts in ultra violet light has been investigated by *Brown* (Pros. Roy. Soc., Edin., 1913, *33*, 44). The salts examined were the chlorides and bromides, and in the case of copper, the sulphate, observations being made over the region $\lambda = 265\ \mu\mu$ to $\lambda = 450\ \mu\mu$. The calculated molecular extinction coefficients are plotted against the wave-lengths, and the resulting curves are compared. *Jones* and *Anderson* (Amer. Chem. J. 1909, 41, 163 and 276) have obtained photographic records of the absorption spectra of solutions of cobalt chloride, bromide, nitrate, sulphate, thiocyanate, and acetate, and of nickel, cupric, ferric, and chromic chlorides. The ultra violet absorption exhibited by aqueous solutions of cobalt salts diminishes with dilution and increases with rise in temperature. *Anderson* (Proc. Roy. Soc. Edin., 1913, 33, 35; J. Chem. Soc. 1913, Abs. 104, ii, 454) has investigated the light absorption of aqueous solutions of ferric chloride, bromide, nitrate, and sulphate, and ferrous chloride and sulphate. *Massol* and *Faucon* (Compt. rend., 1913, *157*, 332) have made a study of the absorption of the ultra violet rays by aqueous solutions of such substances as potassium ferrocyanide, gold chloride, copper sulphate, etc. These bodies exhibit various powers of absorbing ultra violet rays, and are far less powerful than synthetic organic dyes although qualitatively the absorption is of the same order, and in the case of band spectra, broad absorption bands occur in the same regions of the spectrum, these depending on the color, and not on the chemical constitution of the substance. An attempt was made by *Jaeschke and Meyer* (Zeitsch. Physikal. Chem. 1913, *83* 281) to find a relationship between the color of derivatives of manganese compounds and the valency it is exhibiting in these compounds. For this purpose the absorption spectra of potassium permanganate, potassium manganate, the doubtful manganese tetrachloride, manganic chloride, manganic sulphate, manganic phosphate, manganous chloride, and manganous sulphate were determined. *Jaeschke and Meyer* state that the violet end of the spectrum is most sensitive to changes in valency, but that they are unable to make any measurements in that region or in the ultra violet portion of the spectrum. *Walter* (Physikal. Zeitsch., 1912, *13*, 6) has obtained photographs of the absorption spectra of the phosphorescent alkaline earth metal sulphides containing bismuth as "active impurity." The spectra are characterized by strong absorption bands.

Organic Nickel Compounds.

The nickel derivatives of methyl and ethyl-nitroamines have been prepared and their absorption spectra compared with that of nickel nitrate by *Franchimont* and *Backer* (Rec. Trav. chim., 1913, 32, 321; J. Chem. Soc. 1914, Abs., *106*, ii, 83). The absorption curves for the methyl and ethyl-nitroamine derivatives coincide over practically their whole length, and the absorption is complete in the ultra violet. The absorption spectra of some dioximes have been examined by *Tschugaev* and *Glebko* (Zeitsch. Anorg. Chem., 1914, *89*, 241) by means of a quartz spectrograph. The dioximes of nickel exhibit absorption in the visible and ultra violet region, the characteristic band having its maximum between $1/\lambda$ 3,500 and 4,000. The ∝ dioximes themselves have only continuous absorption. Cobalt palladium and platinum dioximes also exhibit absorption in the ultra violet region.

In determining the absorption spectrum of twenty complex cobaltammine salts, *Luther* and *Nikolopulos* (Zeitsch. Physikal. Chem., 1913, 82, 361) measured the visible portion of the spectrum by a spectrophotometer using a mercury vapor lamp as the source of light, and the ultra violet portion was measured by Hartley's method using a quartz spectrograph and an iron spark as source of light. The various errors of the method are discussed, and an approximate estimate of their dimensions is made. It is shown that the light absorption is dependent on the composition of the complex. The replacement of NH_3 by NO_3, H_2O, Cl and Br in the complex causes a displacement of the absorption towards the red end of the spectrum. Replacement of NH_3 by NO_3 causes a displacement toward the violet end.

Shibata and *Urbain* (Compt. rend., 1913, 157, 593) have made a study of the absorption spectra of solutions of twenty-four complex cobalt salts in the visible and ultra violet portions of the spectrum, the results pointing towards certain relations between the constitutions of the complex salts and their absorption. Curves obtained by plotting the thickness of the solutions against the frequency limits of absorption show two decided minima in the neighborhoods of λ 2,000 and λ 3,000. These two bands seem to be characteristic of the tervalent cobalt atom functioning as chromophore.

Guy and *Jones* (Amer. Chem. J., 1913, 50, 257) have studied the absorption spectra of salts of neodymium, praseodymium, nickel and cobalt, and compounds of the latter element were found to have a strong ultra violet absorption.

Hantzsch (Ber. 1908, *41*, 1216) investigated the intensities of solutions of hydrogen platinichloride and sodium platinichloride of widely varying concentrations and in various solvents. These substances were chosen as objects for investigation because they contain the completely saturated complex $PtCl_6$, and are consequently not affected by the solvent. It is found that equivalent solutions of the acid and of the salt in the same solvent are optically identical, that is, show the same absorption spectrum, and that the molecular absorption is independent of the degree of ionisation.

A New Aniline Black with a Titanium Base

By Ellon R. Darling

FROM time to time there has appeared a number of methods for the production of aniline blacks. Some recommend the use of one bath and others two baths. Both methods have their advantages. In most of the two bath methods sodium chlorate and hydrochloric acid are used in the first bath and sulfuric acid in the second. But it must be remembered in considering the respective merits of the various methods that the action of mineral acids upon cotton is not of the best and it is necessary in most cases when mineral acids are used in the treatment of cotton goods to take the utmost precaution to prevent the injury to the tensile strength of the materials being treated. Even under the best of conditions a slight tendering is likely to result. Losses of as much as 21% in tensile strength have been discovered by the writer in the course of a number of experiments he has made with aniline blacks made with methods employing mineral acids.

The writer has found that by making use of a low priced organic acid much of the trouble now experienced with aniline blacks can be eliminated.

A suggested method is as follows: A titanium aniline chloride is first prepared. This organometallic salt is insoluable in water but is readily soluble in weak acids. This scale is used as a base for the fixing of the color.

The method the writer used for the dyeing of the color in one bath involved first of all the treatment of the yarn for twelve hours in a five per cent. solution of tannic acid. It was then dried. While the yarn was being treated a bath made up of the following ingredients was prepared:

2%	titanium aniline chloride
3%	aniline oil
15%	44% lactic acid
8%	bichromate of soda
6%	copper lactate

The titanium aniline chloride and aniline oil were first added to the lactic acid and solution effected. Water was then added to volume and the bichromate of soda added (in solution). The whole was well stirred and the copper lactate added after being dissolved in water. The whole was well agitated. The goods to be dyed were then placed in the bath and allowed to remain there for an hour. At the end of that period the temperature of the bath was slowly raised to boiling point and kept there for thirty minutes. The goods were then removed, rinsed and dried.

By this method the writer has found that a jet black color is obtained which possesses all the properties which are obtained when the methods employing sulfuric and hydrochloric acids are used.

The titanium aniline chloride forms an insoluble titanium tannate on the goods which in the present of the oxidizing agent becomes insoluble metatitanic acid. This acid has a strong affinity for the color base and a deeper shade of color is obtained.

A number of trial tests run with the above method and one where mineral acid were employed showed that 25 per cent. more goods could be treated with the same depth of color as when the other method was employed.

Little or no difficulty was experienced when running the method on a commercial scale. Tests run on the tensile strength and the presence of oxycellulose in the fibre showed a marked advantage over the other method.

Tariff Commission Issues Dye and Coal Tar Census

The remarkable success of the American chemists and chemical manufacturers in developing the dyestuffs industry, when the supplies of dyes from Germany were cut off, is strikingly shown in a report just issued by the United States Tariff Commission, entitled "Census of Dyes and Coal-Tar Chemicals, 1917."

At the outbreak of the European war, Germany dominated the world's trade in dyes and drugs derived from coal-tar. Before the war, seven American firms manufactured dyes from imported German materials. In 1917, 190 American concerns were engaged in the manufacture of dyes, drugs, and other chemicals derived from coal-tar, and of this number, 81 firms produced coal-tar dyes from American materials which were approximately equivalent in total weight to the annual imports before the war. The total output of the 190 firms, exclusive of those engaged in the manufacture of explosives and synthetic resins, was over 54,000,000 pounds with a value of about 69 million dollars.

Large amounts of the staple dyes for which there is a great demand are now being manufactured in the United States. A few of the important dyes, such as the vat dyes derived from alizarin, anthracene, and carbazol, are still not made. The needs of the wool industry are being more satisfactorily met than the needs of the cotton industry.

The report gives in detail the names of the manufacturers of each dye or other product and the quantity and value of each produced, except in cases where the number of producers is so small that the operations of individual firms would be disclosed. Seventeen hundred and thirty-three chemists or engineers were engaged in research and chemical control of this new industry, or 8.8 per cent. of the total of 19,643 employees. The report also contains an interesting account of the history and development of the industry since the outbreak of the European war.

Progress in the British and French Dyestuff Industries

In the second annual report of the powerful organization, "British Dyes, Ltd.," there is much of encouragement in the outlook, but emphasis is laid upon the many obstacles in the way of erecting a complete national color industry.

The British company has now a capital of $10,155,000, of which $5,568,000 has been loaned by the Government, and is able to declare a dividend of 6 per cent., the maximum allowed under its charter.

There seems to have been a steady expansion throughout the year. Among the notable advances is the construction of a large factory for the manufacture of azo colors, now in full operation. The manufacture of vat colors has been taken up energetically. Two dyes, a blue and a yellow, of the Indanthrene type, are now regularly supplied and others in this group will soon be added to the list. Several direct cotton colors, a yellow, a violet and a green, have been introduced in this category of dyes, and the range of shades for direct wool colors has been materially enlarged. The output of Methylene Blue has been greatly increased. As is to be expected, the demand for khaki tints—brown, green and yellow—has been enormous, but it has been possible to meet all needs of the English Government, as well as most requirements of allied governments in this connection. The same may be said for all other dyes employed on leather and textiles needed for military purposes. Prominent among these is an alizarin blue of exceptional fastness.

Large installations for the production of b-naphthol and of p-nitraniline have been completed during the year. Several other plants for the manufacture on an ample scale of additional intermediates are nearing completion, and will contribute materially to a much broader range of colors.

Among other features of construction may be mentioned a power gas plant, a 2,000,000-gallon water reservoir, a piping system for the distribution of steam, gas and compressed air throughout the works, an independent electrical installation, a railway system with branches to all buildings. These items illustrate the variety of mechanical factors entering into the evolution of large, self-contained color works.

The chemical staff of the company now numbers 100, and steps have been taken to provide for the adequate training of a number of young men so as to ensure sufficient material for constant increase in the corps of chemists. This provision is in harmony with the plans for erecting a large research laboratory at Huddersfield. Temporarily, advanced investigation, under the direction of the company, is carried on in the laboratories of the Universities of Oxford, Leeds and Liverpool.

This full recognition of the imperative need of high-grade research work if the national industry is to become independent and able to face a multitude of problems in the early future, shows that the management of the company is determined not to repeat the mistake which led to the relative stagnation in British dyestuff industries for so many years.

Two Big Government Acid Plants to Be Erected

Two sulphuric acid plants are to be erected in Pennsylvania under the supervision of the Construction Division of the Army. The estimated cost for both plants is $3,000,000.

One plant will be located at Emporium, while the other will be erected at Mt. Union.

The Emporium plant will consist of eight units on a site which has been selected upon Driftwood Creek, close to the plants of the Aetna Explosive Company and the Emporium Iron Company. In the event that sufficient power cannot be obtained from the plant of the iron company, a one-thousand kilowatt power plant will be erected. The estimated cost of this plant is $2,000,000.

The Mt. Union plant will be erected adjacent to the plant of the Aetna Explosives Company. Twenty acres of land have been purchased at $56 an acre. The contract has been awarded to the Leonard Construction Company. The preparation of all plans and specifications, in addition to the supervision of the work, will be under the direction of the construction division.

These plants will be operated by the Government.

The Mid West Ore Company of Eddyville, N. Y., has been incorporated with an authorized capital of $90,000. The company is authorized by its charter to conduct mining or the manufacture of metals, nitrates and chemicals. The incorporators are A. P. Anderson, B. B. Bachwitz and F. Freeman, all of 34 Nassau Street, New York City.

Chemist Sees Bright Future

(*Concluded from page 422.*)

1917, 134 different intermediates were made by 118 firms. One firm made 63 different intermediates. Dyes were made by 81 firms. The total production of dyes in the United States during 1917 was approximately equal in gross weight to the annual importation before the war. The exports of American dyes exceeded in value, although not in quantity or variety, our imports before the war. The dye industry is not dependent on any imported raw material except sodium nitrate from Chili. Many important dyes are still lacking, but indigo and alizarin are now on the market in significant amounts, and the vat dyes for cotton derived from anthracene are coming.

A new potash industry has also arisen, but its future does not seem so promising as the future of the new dye industry. Here Germany has in inherent geological and geographical advantage. Although shipments from Germany ceased early in 1915, and although prices have advanced to about ten times the pre-war prices, the American production during 1917 was only about thirteen per cent. of our pre-war consumption. This relatively small production was obtained from any sources and by many processes. There is an excellent prospect that the recovery of potash as a by-product of cement mills will survive German competition and ultimately supply about one-third of our needs. In addition significant amounts will probably be secured as a by-product of the pig iron blast furnace. That the other branches of the potash industry can survive German competition is open to serious question.

What Embargoes Did to Trade.

Within a few months after the outbreak of the war, imports to the United States from Germany and her allies came to an end. As the months went by, it became increasingly difficult to obtain cargo space for imports from any part of the world. Now the limiting factor in the American participation in the war is shipping for our troops and their supplies, and therefore ships are no longer free to seek the most profitable cargo and route, but are being assigned to routes and cargoes by the Shipping Board on the basis of military needs rather than profits. The Shipping Board has organized a Division of Planning and Statistics, which is making a study of world commerce and the military and civil requirements, for the purpose of utilizing available shipping in a way that will contribute most to the winning of the war. Military requirements make it essential that an abnormally large proportion of the world's shipping shall be used in the North Atlantic. This has made it necessary to curtail imports from other parts of the world to essential requirements.

W. B. D. Penniman of Baltimore is the chemist on the staff of the Shipping Board. He must decide what chemicals need not be imported at all, and the amounts of others which must be imported to supply essential needs. The importance of this work can perhaps best be made clear by an example. The Shipping Board, after consultation with the Food Administration, decided that ships could not be spared for the importation of tapioca from Java and the Straits Settlements. The War Trade Board accordingly announced that licenses for the importation of tapioca would not be granted. Efforts were immediately made to secure a modification of this order on behalf of manufacturers of nitro-starch for the army, and on behalf of manufacturers of mucilage for the Post Office Department. Nitro-starch which, in the United States at least, was hardly beyond the experimental stage at the outbreak of the war, has been improved until it is one of the safest of all explosives to handle and finds important military uses. Until a few months ago it was made from tapioca. Penniman, however, succeeded in convincing the officers of the War Department and the manufacturers that a satisfactory product could be made from corn-starch. The details of the manufacture have been worked out co-operatively by the starch producers, the manufacturers of nitro-starch, and the experts of the War Department with such success that nitro-starch from corn is not only better but more economically produced than nitro-starch from tapioca. The Post Office Department also readily agreed to use some locally available material instead of tapioca for mucilage on stamps. The shipping saved on this one item of tapioca for nitro-starch is sufficient to transport and sustain in France more than twenty-five thousand fighting men. Mr. Penniman's services to the nation on questions of this character deserves to be better known and appreciated. Imported materials for the time being should be used with the utmost economy and only for essential needs. American chemists can render valuable public service by finding substitutes for materials which must be imported from overseas.

Permanent Value of Discoveries.

It seems probable that many of the discoveries in regard to the use of substitutes for imported materials made under this pressure of war needs will prove of permanent value and have a permanent influence on international trade.

A conference will shortly be held between a committee of the recently formed chemical engineering group of the Society of Chemical Industry of Great Britain and the sub-committee of the council of the society to discuss the relations to exist between the two bodies in the future.

The organization has been formed principally through the efforts of Prof. J. W. Hinchley. Prof. Hinchley in promoting this new organization, expressed himself as believing that the whole chemical industry would benefit as the result of the formation of such an organization as it would serve to indicate the great advancement in the field of chemical engineering.

The Future of Chemistry

(*Continued from page 424.*)

Co-operative effort, one of the most striking aspects of modern life, only became possible when science provided the facilities for municipal power schemes, for telegraphic connection over the whole world, and for the cencentration of production in definite centres. Chemical science is still furnishing the means for further revolutionary changes; during the last few years we have seen great technical developments of purely scientific discoveries—the work of Dewar on the liquification of gases, and that of Cross and Beven on viscose and artificial silk, both of which have led to the profitable utilization of vast amounts of capital—and it is as yet impossible to indicate the ameliorations of the conditions of human life which will inevitably result from contemporary chemical investigation.

In a time of crisis like the present, British custom tends towards the replacement of unreal convention by what is really vital; we have been engaged upon this operation for several years. Whilst previously unheard-of changes have succeeded each other kaleidoscopically in the national constitution, in the political parties in power, in the freedom of the subject, and in hosts of other ways, the nation has recognized that science is the only real maker of history. The whole Empire is now one vast chemical and engineering laboratory, and we even live on a scientific ration of so many calorific units. It is obvious that chemistry, with physics, engineering, preventive medicine, and others of the natural sciences, which previously had no imperialistic position, because powerless to make or break a government, have become the pivot on which turn all our hopes of retaining an independent national existence; it has been suddenly realized that supremacy in these branches of knowledge is vital to our country.

The time is approaching when this state of affairs will change; neglect of the natural sciences will then no longer put us in danger of sudden extinction, but, as was taking place years ago, will lead to our slow certain downfall as a nation. The responsibility is placed upon our scientific men of taking such measures as will ensure that the old order is not re-established, that science makes her voice heard in our national councils, and that policies of drift are forever abandoned.

We have in this country three large and long-established organizetions devoted to various phases of chemical science: the Chemical Society, the Society of Chemical Industry, and the Institute of Chemistry. Is it too much to ask that these three representative bodies, with perhaps the newly-founded Association of British Chemical Manufacturers, and ultimately all the other cognate but more specialized interests, should set up a watchful and alert joint council with directions to consider national questions in which any of the varied interests of chemistry are concerned, and to make such representations to our administrators as would voice the corporate view of the joint body.

I am inclined to think that, had such a body been in existence several years ago, much that has been accomplished in the interval by somewhat devious methods would have been better done. One instance will occur to everyone: that of the much-debated question of the re-establishment of the coal-tar color industry in Great Britain. The scheme adopted by the Government for resuscitating this phœnix in our country, after its past thirty years of profligate productivity on the Continent, was launched without scientific advice; the Cabinet mouth-piece, indeed, declared that the directors of the company was not to include men of scientific knowledge, on the ground that a director who knew something about the business of the company would have an advantage over his less well-informed colleagues.

Owing largely to the fact that we possess no strong collective council, representing the combined academic, scientific, and industrial aspects of our science and capable of representing them before a representative Government, it may be argued that we chemists are not altogether blameless for the particularly blundering way in which particular errors have been perpetrated by the responsible officials. Whilst we should be thankful that our blunders have not led to our destruction, we should proceed without further delay so to organize the resources of chemistry as to make it possible to enforce the adoption of scientific methods and modes of thought by authorities to whom these are yet strange.

The serious character of the British position in connection with the coal-tar color industry becomes more evident when one considers that this is a key industry, upon it depend the textile, paper, photographic, and pharmaceutical industries. The total capital employed in the organic dye industry in Great Britain is between four and five million pounds, whilst the capitalization of the German coal-tar color firms is of the order of fifty million pounds. The need for greater and more intelligent activity in this direction is obvious; unless national enterprise can be stimulated into providing adequately for the manifold requirements of Great Britain and her Colonies in all those industries which depend on coal-tar color manufacture, we shall be again in the hands of the foreign producer.

The control of a national dye scheme by business men with no real feeling for the enterprise on which they are engaged renders it fairly certain that the wider aspects of coal-tar color manufacture will be neglected. The interweaving of the color interests with those of synthetic pharmaceutical, photographis and other chemical industries is essential to success. The utilization and development of the resources of the Empire in natural coloring matters such as indigo is necessary from a national point of view. The careful study of our own and other codes of Patent Law in their bearings upon the fine chemical industry is also important. These weighty questions cannot receive adequate consideration from any purely lay body.

One aspect of this question, however, calls loudly for attention. For several years past our teaching staffs have been depleted, and but a small fraction of the normal number of young men have been able to present thtmselves for training in chemistry. Whilst the present demand for capable young chemists is vastly in excess of the supply, an even more serious situation awaits us in the future. If hostilities were to cease to-morrow, five years would be needed before our colleges and universities could begin to supply the large numbers of young chemists which will be required for the development of the future great chemical industry of this country.

Surely this is a matter which should engage the serious attention of the country. If it proves necessary to import young chemists from neutral nations to man our reconstruction schemes a handicap will be established which we may never outrun. The adoption of some scheme by which a sufficient number of juniors can be provided to help in the great developments which the future has in store for the scientific industries of the country is of the utmost importance.

Chemists Must Co-operate More.

It is impossible to reflect on the desirability of a closer co-operation between the large societies representing chemistry in Great Britain without foreseeing many directions in which such a union would be of value. As in every time of awakening, there exists at present a great feeling of unrest among the younger members of our profession; of late quite a number of propositions for the formation of new scientific societies have been promulgated, and all for the purpose of placing more power in younger hands and for ensuring to the juniors more security of advancement. The final objects of these propositions, so far as I have understood them, are entirely praiseworthy, but it is to be feared that the methods suggested for their attainment are not always such as appeal to older and more experienced people as likely to prove successful. If we chemists collectively were in possession of some more centralized organization, such an one, for example, as is represented by the Chemists' Club in New York, with facilities for hospitality, meetings, library, laboratory accommodation, and the like, no question could ever arise of the creation of a new chemical body unconnected with the main organization. A new and vigorous issue of the parent organization would shoot at appropriate intervals, and would remain contributing to the strength of the family under the original patriarchal roof. We greatly need a central home of all the chemical interests in the country, and premises several times as large as the Chemical Society rooms, to use as a club, of which every chemist in the country would be a member. The question of the necessary expansion of the library, which is occupying the earnest attention of your Council, would find an easy solution in such a pooling of interests.

Notwithstanding that, during the past forty years, much has been done to facilitate the entrance of talented and promising young men into the scientific professions, far more progress must be made in this direction if we are to regain for Great Britain the paramount position she once held in scientific discovery. The Natural Science Department in every university in the country call for expansion in personnel, laboratory space, and equipment, and in provision for post-graduate research work; whilst scholarships for students in training are fairly plentiful, the difficulties which face the advanced student who needs to spend, and who would benefit immensely by spending, several years on original research, are often insurmountable. Every professor of chemistry in the country can recall many instances in which he has had to send his students into technical life at too early a period, simply because it has been impossible to secure for a good man the £150 or £200 per annum necessary for living expenses; the provision of this small sum would, in many cases, convert a half-trained chemist into a far greater asset to the State.

Scientists Must Be Better Paid.

The fact emerges that if science is to retain in its service such a proportion of the most powerful intellectual and creative talent of the Empire as will suffice for our progress as a nation, some method must be devised for securing to its followers appropriate emoluments commensurate with those now allocated to the non-productive profesions.

This is not only necessary in connection with those purely utilitarian branches of chemical science to which I have already directed attention, perhaps too insistently for illustrative purposes. A great danger exists at present, and will grow in the futre, that the enormous productiveness of experimental science will overshadow the importance of scientific work of less immediate utility. It would be a great calamity if pure science were neglected in favor of the cultivation only of natural knowledge which gave immediate promise of beneficial material results. One of the most important functions of any expression of collective chemical interests such as I have foreshadowed would be to ensure that pure unproductive scientific research should be retained on an even higher level than that assigned to immediately productive original investigation.

At the present time, physics and chemistry are merging into one; we foresee that the near future will furnish us with still broader views of the universe and will mark a new development more illuminating even than the great advances followed Dalton's atomic theory and all its nineteenth century sequences. No material interests must be allowed to check this stupendous expansion of our knowledge.

The White Tar Aniline Corporation has been incorporated with a capitalization of $100,000. The incorporators are A. A. Haase, Montclair, N. J., J. J. Scheuch, 610 116th street, Manhattan, L. S. Landers, 15 Fort Washington avenue, Manhattan.

Ultra Violet Light

(*Continued from page 426*)

The light absorption of the acid and of the salt is also unaffected by changes of temperature. The solvent does not appear to exercise any influence on the absorption in the blue and violet parts of the spectrum, but does so to a very slight extent in the green and ultra violet.

Organic Platinum Compounds.

Hantzsch (Ber., 1911, *44*, 3290) has investigated the ultra violet absorption of a number of aliphatic ammonium salts in order to determine whether these exist in valency-isomeric forms. The existence of such valency-isomerides is indicated by two modifications of dimethylammonium platinichloride. In all solvents the molecular absorption of the alkylammonium salts is independent of the concentration, so that no evidence of the existence of valency-isomerides was obtained. From the independence of the absorption and concentration, the conclusion is drawn that neither association nor disassociation has any appreciable influence on the absorption.

HYDROCARBONS.

Acetylene.

Henri and *Landau* (Compt. rend., 1913, *156*, 697) have made a study of the ultra violet absorption spectra of acetylene, first in gaseous state at the ordinary temperature under a pressure of one-tenth to one atmosphere, using a thickness of 40 cm. of gas, and secondly in alcoholic solution. The ultra violet absorption by acetylene commences approximately at the region where the solar ultra violet spectrum ends. The influence of the acetylene linking on the ultra violet absorption has been investigated by *Stark* and *Lipp* (Jahrb. Radioaktiv. Elektronik., 1913, *10*, 175; J. Chem. Soc, 1913, Abs., *104*, ii, 365) in reference to dipropargyl and acetylene. The extinction curve for dipropargyl shows two well developed bands, the first of which has its head at $\lambda = 245\ \mu\mu$ and the second at $\lambda = 201\ \mu\mu$. The second band is much deeper than the first. It is supposed that the two bands correspond with the pair which have been found to be characteristic of the asymmetric thylene linking. The absorption curve for acetylene exhibits a large number of narrow bands in the region of the second dipropargyl band, the intensity of which increases as the wavelength diminishes. As in the case of ethylene, these narrow bands are only obtained at comparatively high pressures.

Massol and *Faucon* (Compt. rend., 1914, 159, 314; J. Chem. Soc., 1914, Abs., *106*, ii, 695) have examined three specimens of carbon tetrachloride having respectively b.p. 76.2°/762.4mm., 76°/758mm., 76.7°/760mm. Of these, the first two specimens gave broad absorption bands in the ultra violet, while the third showed no absorption band. This specimen was submitted to fractional distillation, and a number of fractions were obtained boiling from 61.4° to 76.3°, all of which showed no absorption band. A final frac-

Growth of Dyestuffs

(*Continued from page 412*)

Speaking of the development of the American dyestuff industry since the beginning of the war in Europe, Dr. Herty said that five dyestuff plants were now engaged in making poison gas for the Government while many others were in various ways contributing indirectly to the manufacture of gas.

Dr. Herty referred in scathing terms to those merchants who still persist in using placards on their goods reading "The color of these goods cannot be guaranteed." It had never been the habit to guarantee all colors, and a great many colors did not need to be fast. Such signs were really lending aid and comfort to the enemy because they, at least, by implication, cast reflections upon the ability of American chemists and manufacturers to turn out dyes which were the equal of the German-made article.

"Assurance of the future of the coal tar chemical industry lies not only with our people as a whole," said the speaker later in his address, "but even more directly with their representatives in Congress, for it must not be forgotten that legislation stands today as a result of the enactment of the 1916 general revenue bill, which is directly in favor of the German industry."

This situation would be remedied, however, Dr. Herty believed, when the forthcoming report of the Tariff Commission on the American dyestuff industry was presented to Congress.

One point the speaker specially emphasized in connection with the question of proper tariff protection for the American dyestuff industry, was the fact that at present, according to the present schedules, intermediates were assessed at one-half the value of finished dyes. Experience, he said, had shown that this differentation was a mistake. The difficult stage of production was from the crudes to the intermediates far more difficult than from the intermediates to the finished dyes.

"And it is in the field of intermediates that dyestuffs, high explosive and medicinals meet upon common ground," continued Dr. Herty. "Furthermore it is evident that when these industries bear the brunt of foreign attack the enemy will take advantage of questions of definition to avoid the higher duties or to seek to achieve the same purpose by shipping the lower assessed intermediates for assemblage here into finished dyes by simple processes requiring little outlay.

"Knowing where the attack will be made, would it not be the part of wisdom to strengthen our forces at this point by legislation which will place all of these products on the same dutiable basis."

Searles Lake Basin

In the course of a detailed description of not only the topography of the Searles Lake Basin, but of the methods used by the American Trona Corporation to extract potash from the saline waters of the lake, Alfred de Ropp, Jr., research engineer for the corporation, said that the America Trona Corporation is producing about 1,800 tons of crude potash per month from this source. By the end of the current month, thanks to the installation of new equipment devised under the direction of Dr. H. W. Morse, the corporation will be able to turn out about 4,500 tons per month. This product will analyze from 75 to 80 per cent. potassium chloride and will contain less than 3.5 per cent. borax, figured as anhydrous sodium tetraborate. By the first of January, 1919, Mr. de Ropp said the company would be producing some forty to fifty tons of refined borax, thanks to installation of new equipment.

DU PONT AMERICAN INDUSTRIES

DU PONT DYESTUFFS

Explosives to Dyes

The evolution from explosives to dyes is the logical development of the dyestuff industry from both a chemical and engineering standpoint. The manufacturer of explosives enters upon the production of coal tar dyestuffs with these important advantages:

First, the explosives manufacturer starts with the necessary raw materials. In his munitions plants he produces the bases which are required. The immense output of his acid plants is at his disposal. In his chemical factories he manufactures many of his principal intermediates. He is therefore assured of sufficient quantities of the required ingredients—all products of this country—to meet his various needs.

He has at his command unequaled plant and laboratory facilities for the production and development of the intricate by-products of the coking industry, equally useful in the making of military high explosives and in the manufacture of dye intermediates and dye-stuffs.

His chemical and engineering organization has had long training in the closely related explosives industry and is able through the experience gained, to overcome difficulties which would be insuperable to others less fortunately situated.

The high quality of his raw materials is guaranteed because they are made under his constant supervision and control and under the very exacting requirements of the explosive industry. He is consequently able to maintain, as no other manufacturer, the high standard of his finished product. As the world's largest manufacturer of explosives the Du Pont Company enjoys these advantages to an unusual degree. It has already made possible the laying of a broad and secure foundation and the development of dyestuffs of the greatest commercial and industrial importance. It is the strongest guarantee of the permanency of our undertaking and of the final emancipation of the dyestuff industry from foreign domination.

NEW PUBLICATIONS

The Lillie Evaporator for Waste Waters

The first booklet relating to the Lillie Evaporator, published by the Wheeler Condenser & Engineering Co., Carteret, N. J., is off the press. The Lillie Evaporator is now manufactured exclusively by this company under agreement with the Sugar Apparatus Mfg. Co., S. Morris Lillie, president, owners of the Lillie patents.

This new booklet calls attention to the factors which make the Lillie Multiple Effect Vapor Reversing Evaporator especially suited to the concentration of waste waters or liquors in numerous industries. Waste waters are often very dilute and the valuable solids form but a small per cent. of their substance. Some of these products have abnormally high values during these war times, and economy of evaporation is now of so great moment. But in normal times financial success or failure may depend largely upon economy of evaporation and it is the normal condition that should be kept in mind. The booklet discusses the "Economy Possibilities" of the Lillie Evaporator, explains the method of "Film Evaporation" discusses the effect of the Lillie Multiple Effect in bringing solutions to "High Densities," explains why "delicate" solutions are less susceptible to injury by heat in the Lillie Evaporator, tells how the vapor reversing feature reduces "Incrustation Troubles" to the minimum, refers to the economical "Distillation" of water and lastly, mentions some of the solutions that are not waste waters, but which are successfully handled by Lillie Multiple Effects. Five pages of the booklet are devoted to tables that are of especial value in the evaporation industry. An accordian folding page insert gives the principle instructions for operating Lillie Quadruple Effects.

Centrifugal Boiler Feed Pumps

In a pamphlet entitled "Centrifugal Boiler Feed Pumps," the De Laval Steam Turbine Co., Trenton, N. J., describes the De Laval combined steam turbine and centrifugal boiler feed pump. Centrifugal pumps have been used for feeding high-pressure steam boilers for a number of years, but the machine here described differs from those previously used in that the steam turbine rotor and the pump impellers are mounted upon one shaft with only two bearings and are enclosed within one housing. The combined turbine pump casing is split horizontally and by lifting the cover all internal and working parts are exposed. The steam and water connections are in the lower part of the casing and are thus not disturbed when the pump is opened. The turbine is of the velocity-stage type and the pump contains either two or three impellers, according to the boiler pressure.

One of the most remarkable features is the extremely small size and weight of this type of pump. A pump for 3,000 boiler horse power occupies a floor space of only two by three feet as against about eight times that space for an ordinary duplex pump. Turbine-driven centrifugal pumps in one housing are made in capacities from 2,000 to 10,000 boiler horse power. For larger units up to 60,000 horse power the pump and turbine are built separately, but mounted upon a common base plate. The pamphlet also describes electric motor-driven units.

USING NEW CELLULOSE YARN

(*Continued from page* 417)

and cotton necessary for the mixture we shall undoubtedly be able to get these from other sources of production."

That some at least of these obstacles to the free manufacture of cellulose yarn, by German textile mills, have apparently already been removed, may be presumed from an extract from the *Rheinisch-Westfalischen Zeitung,* quoted in the Commerce Reports of the Bureau of Domestic and Foreign Commerce. This statement reads:

"The negotiations between the Government clothing department and the Vereinigten Glantstoff factories in Eberfeld seem finally to be coming to an end. The factories have declared themselves willing to give free their patent rights for the manufacture of cellulose yarn. This will probably mean that several hundred textile factories in Saxony, Thuringen, Silesia and Rhineland Westphalia without any technical difficulties or changes will be able to weave this new yarn. This will relieve the shortage of material. It is hoped that in a short time it will be possible to push the manufacture so much that large quantities of cellulose yarn will be ready this fall to hand to the weaving mills."

The Century Chemical Company has been incorporated under the laws of Delaware by F. D. Buck, M. A. Davis and J. D. Frick of Wilmington.

* * *

Rogers, Brown & Company, importers and exporters, announce their affiliation with A. R. Hilliard of Seattle, Wash., Mr. Hilliard to take the title of assistant sales manager.

ULTRA VIOLET LIGHT

(*Continued from page* 432)

tion was obtained, b.p. 76.4°/758mm., which gave no absorption band, and was shown to be pure carbon tetrachloride. The others contained carbon disulphide as an impurity, and this produced the absorption band. Neither chloroform nor dichloromethane gave absorption bands in the ultra violet. All three chloro derivatives are colorless, and transparent to the visible and ultra violet rays, only absorbing the rays of very short wave-length. The transparency for the latter rays diminishes as the number of chlorine atoms in the molecule increases.

Benzene, Toluene and Xylene.

An examination has been made by *Kowalski* and *Banasinski* (Arch. Sci. phys. nat., 1912, (iv) 34, 216; J. Chem. Soc., 1912, Abs. 102, ii., 1019) of the absorption of light by ethyl alcohol solutions of aromatic hydrocarbons in the region $\lambda = 210$ to $\lambda = 800$ $\mu\mu$, and at temperatures ranging from —190° to 15°. In the case of benzene, the photographic records show the existence of fifteen bands which may be classified in three groups. The principal group consists of six bands which are equally well defined over the entire range of temperature. The second group consists of two bands, only one of which is seen easily at room temperature, while the second band only is observed at — 190°. The third group of seven bands is found at 190°, but traces only are visible at 15°. The bands given by toluene are more sharply defined at —190° than at the ordinary temperature, and two groups may be distinguished, each of which is characterised by an approximately constant difference between the frequencies of the successive members. At the low temperature the bands are slightly displaced towards the ultra violet end. The absorption spectra of the three isomeric xylenes have also been observed.

(See also Baly, Phil. Mag. 1915, *vi,* 29, 223, who considers the ultra violet absorption spectrum of benzene, toluene, o, m and p xylene and napthalene.)

Toluene.

The absorption spectrum of toluene has been examined by *Cremer* (Zeitsch. wiss. Photochem., 1912, *10,* 349) in the form of vapor at different temperatures and in ethyl alcohol solutions of varying strength. The spectrum of the vapor consists of a series of bands extending from $\lambda = 235$ to $\lambda = 273$ $\mu\mu$, which are shaded off towards the red. The solution spectrum is also banded and the head of the bands are quite independent of the thickness of the absorbing layer and its concentration.

New N. J. Chemical Works.

At Butler, N. J., the Morris County Chemical Works has been incorporated with a capital of $100,000 to operate a plant for the manufacture of chemicals. Incorporators are John A. Marszalek, Thomas L. Sexmith, Wm. Joyce and Walter A. Clark, Butler.

available in your own Laboratory

Every Chemical Laboratory should be equipped with a source of Ultra Violet Rays.

The R. U. V. Ultra Violet Ray Lamp is especially recommended to those chemists who have failed to get desired results with the ordinary form of lamp.

POINTS OF SUPERIORITY OF R. U. V.

As an indication of its superiority, it has been proven that the R. U. V. Lamp yields twice the usual ultra violet component.

The increased radiation insures rapid developments of possible reactions.

The lamp is adaptable to various kinds of vessels. High efficiency is assured by manufacture of frame from new and clear quartz exclusively.

There is perfect electrical control.

New Publications 471

Statement of the Ownership, Management, etc., Required by the Act of Congress of August 24, 1912.

Of the Chemical Engineer, published monthly at New York, N. Y., for October 1st, 1918.
County of New York, State of New York, ss.

Before me, a Notary Public in and for the State and county aforesaid, personally appeared Robert H. McCready, who, having been duly sworn according to law, deposes and says that he is the Publisher of the Chemical Engineer, and that the following is, to the best of his knowledge and belief, a true statement of the ownership, management (and if a daily paper, the circulation), etc., of the aforesaid publication for the date shown in the above caption, required by the Act of August 21, 1912, embodied in Section 443, Postal Laws and Regulations, printed on the reverse of this form, to wit:

1. That the names and addresses of the publisher, editor, managing editor, and business managers are: Publisher, McCready Publishing Co., 118 East 28th St., N. Y.; editor, A. G. Sclater, 118 East 28th St., N. Y.; managing editor, none; business manager, H. C. Daych, 118 East 28th St., N. Y.

2. That the owners are: C. J. O'Brien, 22 North William St., N. Y.

3. That the known bondholders, mortgagees, and other security holders owning or holding 1 per cent. or more of total amount of bonds, mortgages, or other securities are: None.

4. That the two paragraphs next above, giving the names of the owners, stockholders, and security holders, if any, contain not only the list of stockholders and security holders as they appear upon the books of the company, but also, in cases where the stockholder or security holder appears upon the books of the company as trustee or in any other fudiciary relation, the name of the person or corporation for whom such trustee is acting is given: also that the said two paragraphs contain statements embracing affiant's full knowledge and belief as to the circumstances and conditions under which stockholders and security holders who do not appear upon the books of the company as trustees hold stock and securities in a capacity other than that of a bona fide owner; and this affiant has no reason to believe that any other person, association, or corporation has any interest direct or indirect in the said stock, bonds, or other securities than as so stated by him. ROBERT H. McCREADY.

Sworn to and subscribed before me this 30th day of September, 1918. FREDERICK PFISTER.

NOVEMBER, 1918

SINCE its foundation seventeen years ago, it has been the aim of The Chemical Engineer to serve its readers in every way possible. Today faced as the country is by industrial and commercial problems more difficult of solution than any it has perhaps ever faced before, The Chemical Engineer feels that its opportunity for service is greater than ever. We therefore, wish to call our readers attention to the fact that our columns and our services are at their disposal at all times. So far as the use of our columns are concerned, we believe we can be of service as a medium from time to time for the expression of opinion regarding matters touching the welfare of any of the various chemical industries.

Most of our readers are either chemists or manufacturers: most of them have problems they find difficult of solution. To these we offer our services. If they will but write us a detailed account of their problems, we will do our best to put them in touch with those who can give them the best scientific advice obtainable.

THE imminent, declaration of peace will bring the fertilizer industry of the country face to face with a situation demanding careful handling on their part and on the part of the Government. Today the industry is managing to subsist on war time rations of potash, for the greater part derived from American sources. In spite of the most intensive development of all possible sources of supply, it is hardly likely that more than twenty percent of the country's normal potash requirements will be available from these sources during the coming year. As is well known the soil of many of the southern states have been seriously impoverished during the past two years, by the farmers' inability to obtain anything but low grade fertilizers with a very low potash content. It is likely that with the increased demands to be placed upon the country's agricultural resources during the next year or so, this potash famine will become increasingly serious. To enable the farmers of the United States to turn out the greatest possible amount of produce during the coming few years, where is the potash coming from?

Is the fertilizer industry of this country to acknowledge the truth of a recent expression of opinion of a chemist in the Government employ, that so far as the potash industry is concerned Germany has inherent geological and geographical advantages over the United States? And that we will be compelled in the future to look to her for a great part of our potash as we did in the past?

Granting that the fertilizer industry will be compelled in the not far distant future to resume its use of German potash, may it not be expected that a certain proportion of the distaste with which such a step will be viewed by many in this country, will be mitigated by the thought that such an action would be taken purely and simply from a desire to increase the food and raw material supplies available in the United States?

AMONG technical men almost universal approval will be expressed of the recommendation recently made by the United States Section of the International High Commission, regarding the more extensive use of the metric system in the trade and commerce of the United States. This approval will be heartily seconded by a great many American manufacturers.

Only the English speaking nations still have to adopt the metric system of measurement. With the exception of Great Britain it is universally used in Europe and Latin America long since made it official. Great Britain is believed to be seriously considering its adoption. Why not the United States?

Quite apart from the saving of time, in the internal commerce of the country, which would inevitably result after the system has been in use for some little time in this country, the adoption of the metric system would facilitate the processes of international commerce, to a remarkable degree.

Two thirds of the countries of South America have already signified their acceptance of the treaty recently signed between the republics of North and South America, making it possible to issue Pan-American patents.

Industries Face Future Optimistically

Manufacturers and Chemists Tell Chemical Engineer American Industries Can Regard Future Hopefully —War Industries Board to Issue Statement Shortly.

WHILE to the general public and a considerable proportion of the manufacturers of the country, the signing of the armistice which brought the hostilities in Europe to a close came with a suddenness almost stunning in its effect, for months back a certain far-sighted section of the business men of the country and most of the Government departments having anything to do with the regulation and control of business, have been preparing for the coming of peace. This minority, faced with the problems of the reconstruction period, did not exhibit the same degree of uncertainty in regard to the future that many did. Having faced the worst in advance, they regarded the announcement of peace with a certain degree of calmness.

Today members of the chemical and allied industries in all parts of the country, judging from communications received since the signing of the armistice by The Chemical Engineer, regard the possibilities of the future with considerable optimism. Some of these expressions of opinion are printed below.

In anticipation of peace, the Chemical Division of the War Industries Board, under the guidance of Mr. Charles H. MacDowell, has within the past few months been quietly doing a great deal of very effective work in the direction of standardizing and developing chemical manufacturing methods in this country.

In answer to our request for a statement regarding the nature and extent of this work, Mr. MacDowell writes that at the moment his division is not prepared to make a statement, although considerable work has been done. Such a statement is, however, being prepared by the heads of the various sub-divisions of his section of the War Industries Board and this will shortly be made public.

What some of the men in the chemical industries feel regarding the future is obvious from the following letters.

Thomas J. Keenan, secretary-treasurer Technical Association of Pulp and Paper Industry:

The war in Europe has opened the eyes of American pulp and paper manufacturers to the possibilities of a great expansion of effort in the production of certain kinds of pulp, paper and paper products. Already our manufacturers are suplying different grades of paper products that were formerly purchased in foreign markets, and a considerable export demand has sprung up, especially from the countries to the south of the United States and from the Allied Nations.

With the resources of raw material still available on the American continent there should be a tremendous development in the manufacture of chemical pulps, especially those made by the modified soda method known as the sulphate process which are used so extensively in the manufacture of wrapping paper and boards, not to speak of many special papers having a kraft basis. An indication of this is given in the enterprise of certain Norwegian pulp manufacturers who are now engaged in establishing plants both in this country and in Canada for the development of our pulp resources.

With the approach of peace every means possible should be taken to interest capital in the development of a strong American paper industry. If the opportunity is neglected by our people it will not be passed by others, as there is a fierce competition impending among all the countries now at war, and it is of vital importance that we should take immediate steps to insure a greater consumption of our own raw material and a corresponding increase in exports of the finished products.

Alfred D. Flinn, secretary of the Engineering Foundation:

A greater degree of co-operation is needed between chemists and other technical men qualified to conduct research work, if the country is to prepare itself to meet the problems of the coming reconstruction period.

Co-operation in industrial research is especially important in these times to chemists and all other technical men. It is also important to make the results of research available, so as to reduce wasteful duplication of work. There are approximately four hundred industrial laboratories in the United States, little and large, devoting some part of their time to research in distinction from routine tests and investigations. Many laboratories, however, and the companies supporting them, have not sufficient resources to undertake needed researches. In many of these cases co-operation within an industry or a group of kindred industries may provide sufficient resources not of funds alone, but also of technical skill, special materials, experience and equipment.

John C. Bailar, Golden, Colorado:

When the present world war cut off the supply of chemical and scientific porcelain it became necessary for our manufacturers to supply the need. Three factories were soon in the field—the Coors Pottery of Golden, Colo.; the Guernsey Company of Cambridge, Ohio, and the Ohio Pottery Company of Zanesville, Ohio. It took but a short time to demonstrate that American manufacturers could satisfactorily supply all needs.

For some years past we have excelled European manufacturers in coarser work, such as fire brick, assayers, crucibles, etc., but it was not thought possible to compete with them in the finer grades of work such as chemical porcelain, until we were forced by necessity to try it. We have demonstrated now beyond all doubt that we have the skill and the raw material to make as good ware as is made in any part of the world; and it can be safely predicted that with the coming of peace the manufacturers of the United States will not only supply the home market, but will compete with foreign manufacturers for the trade of the world.

H. Walker Wallace, Manager, General Sales Department, Virginia-Carolina Chemical Company:

We chiefly manufacture commercial fertilizers and concentrated superphosphates. Incidental thereto, we produce sulphuric acid; also other chemicals and by-products.

War necessities have required a production of sulphuric acid and other chemicals in this country considerably in excess of normal consumption. The post-war problem of utilizing the surplus will be a serious one. Domestic requirements for chemicals will doubtless be greater than heretofore, and will absorb part of the excess. Part may also be used by the fertilizer industry as a means of augmenting the production of food and other farm products that will be needed in the process of readjustment and rehabilitation.

However, there must be additional outlets for the surplus through greater development of foreign trade. The possibilities for American enterprise along this line are practically boundless. The permanency of our spuremacy will be measured by the efficiency with which we meet this situation, and nurture foreign and domestic requirements. We should lose no time in directing our diligent attention to this.

Charles A. Doremus, M.D., Ph.D., Consulting Chemist, Secretary New York Section, Societe de Chimie Industrielle:

The only true basis on which the independence of our country can rest are agriculture and manufactures. "To the promotion of these nothing tends in a higher degree than chemistry," said Thomas P. Smith, in an annual oration delivered before the Chemical Society of Philadelphia, April 11, 1798. "Our nation is now thoroughly aroused. Since pressure has been put on us we have learned lessons of efficiency impossible to forget.

"We now realize that our economic life is dependent on science. Until now our inventions have chiefly related to civil and mechanical engineering. The future holds out amazing possibilities to those who are pioneers in things essentially chemical."

A manufacturer of chemicals, who would not allow his name to be used, writing of after-war conditions, says:

A third source of war disturbances in the chemical industry has been due to the diversion of materials from their customary use to war uses. The fertilizer industry has probably made the greatest sacrifices of this sort. Sodium nitrate and ammonia are required for the manufacture of explosives in such large quantities that the amounts left for use in fertilizers has been and will be much reduced. Raw phosphate rock has of course been plentiful but the acid used in the manufacture of acid phosphate has been largely diverted to making explosives. The relatively small supplies of potash have been very high in price and normal amounts have not been available at any price. The peace readjustments may, however, be expected to bring compensation to the fertilizer industry. Large new supplies of nitrogenous fertilizer materials will be available from the new nitrogen fixation plants. The new and enlarged sulphuric acid plants must again find the chief outlet for their product in the making of fertilizers. Finally the German monopoly of the potash market is likely to be broken through the French control of Alsace and the new developments in America and Spain. It is therefore reasonable to expect a large increase in the manufacture and use of fertilizers with a resulting benefit to all producers and consumers of food.

The coming period of peace will offer to the American chemist and the American chemical engineer, an opportunity such as never lay within his reach before. If there is one thing that the present war taught our merchants and our manufacturers, it has taught them the necessity of scientific precision. The elimination of waste, whether of labor or materials has been forced upon America as a measure of national self preservation. But while the need for efficiency and economy has been learned to a great extent, the methods of attaining these two highly desirable industrial virtues has in many cases yet to be learned. It is here that the chemical engineer's opportunity lies.

Even though the war is over, the necessity for efficiency and economy still exists. For peace has come to find a world disorganized.

To Discuss Reconstruction Problems

War Service Industrial Committees Will Meet for Conference in Atlantic City

Plans for assembling at Atlantic City December 4, 5 and 6, all members of the country's more than 300 industrial war service committees for a great war emergency and reconstruction conference have been announced by the War Service Executive Committee of the Chamber of Commerce of the United States.

The meeting will bring together from 2,000 to 3,000 industrial leaders to discuss problems that have arisen with the war. National councillors of the Chamber, representing the more than 1,100 commercial and industrial organizations which comprise its membership, will meet at the same time and place.

The main purposes of the conferences will be the determination of practical methods whereby industry may cooperate still more closely with the Government through a more centralized scheme of organization. This probably can be accomplished best by the creation of a federation of all the war service committees. Questions of reconstruction, too, will be taken up.

For nearly a year the Chamber has been engaged in directing the organization of war service committees in all lines of industry to assist the Government in mobilizing most effectively the country's industries for prosecution of the war. It is evident that however far away the end of the war may be it is necessary to begin to outline a general program of organizing business for the period of reconstruction.

Single industries, acting individually, can scarcely hope to prepare for reconstruction on the scale that will be necessary and a federation of all the war service committees of all the industries will be of inestimable value in co-operating with those agencies of the Government to be created to deal with this subject.

The war service committees represent the most important and best informed body of business men ever associated for a practical and patriotic purpose and the conference therefore will be one of the most important business gatherings ever held in this country.

Certain common interests and duties that bind together all the war service committees include: War Industries—To keep efficiency and production at the highest possible point through stable labor conditions and steady flow of materials through plants, thus assuring the utmost aid in carrying out the war program of the Government. Non-War Industries—To keep plant organization and production from falling below the danger line in the face of shortage of materials, labor and transportation. Jointly—To face squarely and constructively the reconstruction period and to be ready through accurate and exhaustive study to lay before such Governmental agencies as may be created to deal with reconstruction the necessary data bearing on the subject.

Questions foremost at this time in the minds of every business man will be discussed at the conference by the best authorities that can be assembled. Speakers who already have accepted invitations to appear include Secretary of Commerce William C. Redfield, A. C. Bedford, James A. Farrell and Paul Warburg.

The conferences will include general sessions at which questions common to all industries will be taken up, sessions of committees within particular industries at which specific industrial problems will be discussed, meetings of related war service committee groups, and conferences of individual war service committees. National councillors of the Chamber of Commerce also will hold separate sessions.

The main conferences will be held on the Million-Dollar Pier.

Willard E. Case Passes Out

The recent death of Willard E. Case at his home in Auburn, N. Y., removed from the ranks of the electrochemists of the United States a figure of international importance. Descended from a long line of scientists, he devoted his life and wealth to the service of science, capping the achievements of a lifetime by handing over his splendid laboratories at Auburn, probably the finest in the country, to the service of his country when war broke out. A staff of Government electrochemists are now using the laboratories for the conduct of war research work.

In October of last year Mr. Case made what was said to have been the largest endowment in years for similar purposes to the New York Electrical Society to be known as the Case Fund, to be used for war research work in electricity.

The late Mr. Case was born in Auburn, N. Y., in 1857, the son of Theodore P. Case. He married in 1878 Miss Eva Caldwell, who with a son and daughter survive him.

To contend with a growing shortage of nitroglycerin explosives in South Africa, Kynoch, Ltd., have evolved at their Umbintwini, Natal, factory, a new explosive known as sengite. This new material has a gun cotton base and made by the manufacture of tonite in which nitrate of soda is substituted for the nitrate of barium usually made use of in the manufacture of tonite. Sengite has approximately the same strength as gelignite.

Coke Makers Now Make Nitrate of Ammonia

English Research Proves That It Is Commercially Possible to Turn Ammonia By-Product of Coke Ovens Into Nitrate of Ammonia.

By **MARK MEREDITH, M. E. A., M. I. S. A.**

OWING to the scarcity of sulphuric acid in the chemical world, nitre cake has been tried for mixing with acid to make sulphate of ammonia, but it is hardly suitable, because of the considerable admixture of sodium sulphate and recent research has proved that it will be possible in the future for the makers of coke to easily turn their ammonia by-product into nitrate by means of acid of their own manufacture.

The process is naturally a lengthy chemical one and needs specially designed plant, but the nitric acid required for nitrate of ammonia may be very dilute—of, say 25 per cent. to 33 per cent. strength—and it is easily and cheaply made from the air, by electric power. The process is not new, because nitric acid has been made from the air on a very large scale for many years in Norway, Italy and France, and one of the most striking scientific developments of the war has been the way in which some countries, by fixation of atmospheric hydrogen, has become entirely independent of Chili nitrate and of sulphuric acid. Atmospheric nitrogen can be made in two ways: First, as ammonia, and secondly, as nitric acid. Ammonia can be made.

(a) as a by-product in the manufacture of coke in regenerative and in waste heat ovens.
(b) as a by-product in the manufacture of lighting and heating gas, for town supply.
(c) as a by-product in the Mond process for production of power-gas from slack coal.
(d) as a by-product in the application of the Mond process to the production of power gas from peat.
(e) as a by-product in connection with distillation of bastard and lignite coals.
(f) as a direct product by acting on superheated steam on calcium cyanamide, which latter compound is obtained by combining pure nitrogen with calcium carbide.
(g) as the direct product of the synthetic combination of pure nitrogen and pure hydrogen in the presence of a catalyst by the process due to Prof. Haber.

Nitric acid can be made in any of the following ways:

(a) The action of sulphuric acid on sodium nitrate or Chili saltpetre. This method is practically universal in the British Isles.
(b) Fixation of atmospheric nitrogen by the direct process using electric arc flames. This method is employed on a very large scale in Norway, and is used in Italy, France, Switzerland. A factory is to be built in Manchester.
(c) Oxidisation of ammonia in the presence of catalyst by the process due to Prof. Ostwald. This method is employed on a large scale on the other side, and is also in use in Italy, France and Belgium. A small plant has been built at Dagenham Dock, in Essex.

The various methods of making ammonia and the nitric acid into nitrate of ammonia are briefly as follows:

1. By direct mixing of strong ammonia with strong nitric acid made from nitrate of soda. This method is employed by Chance and Hunt.

2. By the reaction of sulphate of ammonia with calcium nitrate or nitrate of soda. This method is employed by Brunner, Mond & Co.

These are purely chemical methods, whereas the two following depend upon the use of catalysts.

3. By the combination of ammonia made from calcium cynamide, with nitric acid made from the ammonia by a catalyst. This method is employed in France, and a factory has been built at Dagenham Dock, Essex.

4. By combination of ammonia made by the synthetic or Haber process, with nitric acid made from the oxidation of ammonia by a catalyst. This method is employed on a large scale in Germany.

There is finally the electrical method.

5. By direct mixing of ammonia solution. with dilute nitric acid of about 25 per cent. strength, made from air by the direct arc-flame process.

For the extension of this last method it has been proposed that gas from regenerative coke ovens or the steam raised by waste heat ovens should be utilized in an electric power house, built by the coke oven proprietor, and some, if not all, energy be employed in making nitric acid from air—this acid to be then combined with ammonia from the ovens to make nitrate of ammonia. This process can be developed at a very low cost at all existing works and its general adoption would mean increased fuel economy.

Nitrate of ammonia is the principal ingredient of most safety mining explosives, the word "safety" being a relative term expressing the fact that they are safer than dynamite, etc. On the Continental Railways, before the war, nitrate of ammonia explosives were considered so safe that they were carried at ordinary rates, but on the British railways have always charged high rates. The British and other governments have passed regulations insisting on only safety or permitted explosives being used in mines, and the more this idea extends the more nitrate of ammonia will be required. Other uses of the nitrate are in burster charges for shells, as an explosive for tree planting, and as a fertilizer.

Before the war Great Britain imported nearly all the nitrate of ammonia for making safety explosives from Norway, and peculiarly enough that country had no coal from which to obtain ammonia, so it had to be sent from England. Ammonia liquor was collected from gasworks and coke oven plants, and concentrated to bring the ammonia up to 25 per cent., and this solution was then railed to Hull, shipped in steel tanks to Skien in Norway and carried a considerable distance up country to the air nitrate factory. As the proportion of water was 75 per cent., the freight, calculated on the real ammonia in the solution was naturally high. The cost of carrying steel tanks, and the heavy depreciation of them was also a great expense, and finally the nitrate of ammonia when made was reshipped from Norway to England, a great deal of it going to Nobel's works in Ayrshire.

Since the war ammonia liquor has continued to be sent to Norway, and nitrate of ammonia brought back, but since the submarine menace this business from England has practically stopped. Ammonia is now being made in Norway by acting on calcium cynide with superheated steam in autoclaives, but the Norwegians prefer the British by-product ammonia as being cheaper.

Before the war Germany was the largest purchaser in the Chili nitrate market, taking twice as much as the next largest customer, the United States, and over six times as much as Great Britain. Now this country does not require any Chilian product, because immense plants to make nitrates from the air have been established. Great Britain, of course, is still completely dependent upon the Chilian product, and thus has to pay large sums for it, its transport and insurance, etc., while large sums are also required for the pyrites, sulphur and for the plants to manufacture sulphuric acid with which to treat the nitrate. The erection of new plants at each coke oven battery would obviate this needless expense and create another new industry, and not only in Great Britain but anywhere at all where coke oven and waste heat ovens are used.

According to the Bureau of Foreign and Domestic Commerce there is at present a good market in Algeria for dyes and dyestuffs. In normal times this market is supplied from Lyon, France. A list of the users of dyes and dyestuffs in Algiers may be obtained from the Department.

The American Chicle Company has purchased additional property adjoining the site upon which it is erecting its new laboratory for the experimental refining of gums, on Hayward Avenue, Long Island City, N. Y.

Many New Companies Formed

Incorporation Records Indicate Steady Increase in Number of Chemical Firms

The Rustanite Corporation, of Manhattan, has been incorporated with an authorized capital of $20,000. The incorporators are D. Sapperfield, W. Eisenbauer, H. P. Nelson, 550 West 157th Street.

The Dye and Chemical Manufacturing Corporation, of Manhattan, has been incorporated by W. C. Sullivan, J. C. Duke, B. B. Mead, all of 1009 Washington avenue, with an authorized capital of $100,000. The company will manufacture potassium permanganate, dyes, explosives, etc.

The Marden, Orth and Hastings Corporation is now in its quarters at 136 Liberty Street. The following allied companies have their New York offices at this address: Calco Chemical Company, United Oil and Chemical Company, Buttersup Oil and Tar Corporation, Edible Oil Company, Inc., Ruhm Phosphate Mining Company, and M. O. H. of the West Indies.

The Brooklyn Potash Company has been incorporated to manufacture chemicals, drugs and dyes, with a capital of $50,000. Those given as incorporators are O. E. Edwards, Jr., 226 76th Street; M. Kiss, 66 Wellington Street, Brooklyn; M. Scott, 173 Wood Avenue, Tottenville, N. Y.

The incorporation is announced from Trenton, N. J., of the Reduction and Concentration Corp. of Birmingham, with an authorized capital of $200,000, and a charter authorizing them to manufacture fertilizers. The incorporators are D. T. Connell, White Plains, New York, and J. F. Roach and O. I. Bahn, of New York City.

The incorporation of the Century Chemical Company, of Paterson, N. J., is announced with an authorized capital of $100,000. The incorporators are Jane D. Keller, William J. Lickel, and Franklin J. Teller, New York City.

The incorporation is announced from Albany of the Process Engineers, Inc., Manhattan, with a capital $200,000, with incorporators as follows: A. J. Kellogg, H. J. Alheim, E. Ackley, all of 15 Broad Street, New York City.

The Eby Chemical Company, Manhattan, has been incorporated with a capital of $10,000. The incorporators are A. A. Friedlander, L. and E. Greenberg, 900 Eastern Parkway, Brooklyn.

The Graham Chemical Company, Manhattan, has been incorporated with a capital of $24,000. The incorporators are P. E. Carroll, B. Kaiser, S. A. Carlson, 1566 East 13th Street, Brooklyn.

The incorporation is announced of the Persol Chemical Corporation, Buffalo, with an authorized capital of $100,000. The incorporators are as follows: L. Owitz, Carlton Court Apartments, L. A. Molin, D. Levin, all of Buffalo.

Preparations are being made by the Capote Nitrate Company, of San Antonio, Texas, recently incorporated with a capital of $100,000, to develop a large nitrate deposit located near Marfa, Texas. The backers of the new corporation are Alfred Dueler, G. C. Simpson, and J. B. Herff, all of San Antonio.

The Stockholm Superphosphate Factory A-B, according to reports from Denmark, is conducting negotiations aiming at the acquisition of the Alby Water Falls, and the Alby Carbide Factory A-B. Nearly all the shares in this latter company are owned in Great Britain. In 1914 The Alby Carbide factory turned out 8,000 tons of calcium carbide and 9,500 tons of lime.

Huns Must Return Stolen Property

New York Section of Society of Chemical Industry Passes Resolutions Demanding Replacing of All Machinery Stolen by German Army in Invaded Countries.

RESOLUTIONS demanding that the German Government be compelled to make restitution for all stolen property and machinery, on the drawing up of the final peace terms, were passed at the meeting of the New York Section of the Society of Chemical Industry held in the Chemists' Club, New York City, on the evening of Friday, October 25. During the course of the war, the German Government, the members present believed, had made systematic attempts by the removal of machinery and workmen to cripple possible industrial competitors. In justice to these competitors and in justice to the rest of the world, who would thus be threatened by a too exclusively German control of certain fields, reparation should be insisted upon.

During the course of the evening Major H. W. Dudley, of the British-American Gas Warfare Service, made an address on "Gas Warfare, Offensive and Defensive," illustrating his remarks with motion pictures of the Woolwich Arsenal, pictures of American gas mask factories and a collection of various types of gas masks.

Major Dudley's address formed a complete history of the development of gas warfare, offensive and defensive. Inaugurated by the Germans in March, 1915, at the first battle of Ypres, and adopted as a consequence by the Allies in September, 1915, the new weapon soon became of such importance, according to Major Dudley, that at one stage of the conflict on the Western front, weakness in the use of either offensive or defensive methods of gas warfare on either side would have meant defeat.

In outlining the history of the evolution of gas warfare Major Dudley said that it had developed in much the same way as the old time competition between the projectile maker and the armor plate manufacturer: the introduction of improvements on the part of one were closely followed by equally important developments on the part of the other.

First Method of Attack.

The first form in which gas was utilized was in the form of the "cloud attack." When this was first used by the Germans in 1915, pure chlorine gas was used. This was stored in cylinders, equipped with siphon tubes running through the centre. These cylinders were carried up by the infantry and placed under the parapets, until needed. To take up escaping gas these cylinders were covered with mats saturated with potassium chlorate. When an attack was to be made pipes were attached to these cylinders and run over the parapet and the gas permitted to escape.

The limitations of this method of gas attack eventually, said the speaker, led to its virtual abandonment Even with the best of discipline and equipment there were inevitably a number of casualties among the attacking troops. Then, too, there were not many gases which were suitable for use in the cylinders. It was found that a gas to be used for such a purpose must have a low boiling point, be toxic, and stable in the sense that it should be difficult for the enemy to find suitable materials to put into their defensive respirators. Then there was also the all-important condition that the gas should be obtainable in enormous quantities.

Another limitation of the gas attack was its dependence on atmospheric conditions. If any degree of success was to be achieved, the most careful weather observations were necessary. There was always the danger than even with the most careful allowance for weather condition, the conditions upon which the success of the attack depended might change at any moment.

Yet another serious limitation lay in the fact that with this method of attack the high concentration was right over your own parapet and that the concentration decreased the farther the gas had to travel.

Surprise Attack Difficult.

There was also the difficulty of obtaining a surprise attack on your enemy. It was a very easy matter for your enemy to discover that you are about to make an attack by the "cloud" method. First, all material had to be carried up. If the gas had any distance to travel the noise of the gas escaping from the cylinders gave the attackers' intentions away. This noise of escaping gas could be heard even when masked by machine gun fire.

In using gas as an offensive weapon surprise was all important, the speaker said, even more important than the two other important factors, that of having a gas which penetrated the respirators and as rapidly as possible exhausted the defensive chemicals of the enemy.

The limitations of the "cloud attack," therefore, led inevitably to the decision to place poison gas in projectiles because in this way the surprise factor was easily obtainable. Further by using projectiles the high concentration of gas was obtained exactly where you wanted it. You were further not so much at the mercy of atmospheric conditions. An additional advantage of this method of gas attack lay in the fact that a wide range of materials could be used in projectiles. It was possible to use materials with a high boiling point and in fact even poisonous solids.

The Germans very early in the war, according to

Major Dudley, began the use of poison shells. They made the first use of them in May, 1915.

There were two main types of gas shells used, first the lethal type, and second the "neutralizing" shells. The first were, of course, used to produce casualties among the enemy, and the second to destroy the morale of the troops on the opposing side. Among the Germans the lethal shells were known as the green cross shells, from the marking made on their base. These usually contained trichlormethyl chloroformate. The "neutralizing" shells, called by the Germans the "blue cross" and the "yellow cross" shells, could be classified into two divisions, according to the effects of the gases they contained as the sterntators and the lacrymators, or the sneezing and tear-producing gases.

Of the three classes of gases the lacrymator, beyond their tear producing qualities, were more or less harmless. The effects of the gas given out by the Green Cross shells were similar to that of phosgen, or the famous mustard gas.

Speaking of phosgen or mustard gas, the contents of the Yellow Cross shells, Major Dudley said that this gas had a high boiling point—over 300 degrees C. It has the advantage as compared with other gases of possessing only a slight smell and was very quick acting. Furthermore, it was at first non-irritating. These qualities made it possible by the use of this gas to take the enemy troops off their guard, as they were often deceived into believing that they did not need their gas masks when attacked. The high boiling point of this gas further made it very persistent. Mustard gas might persist in an attacked area for weeks.

Mustard gas was a very intense skin poison and raised large blisters which were very hard to cure. The lungs, the speaker said, were very sensitive to the influence of this gas.

The Germans had made use of this gas in all sizes of projectiles, from those containing only 200 cc. to those containing as much as 11 litres.

A particular useful method of placing this type of gas in the enemy trenches, according to Major Dudley, was by means of bombs thrown by trench mortars.

Speaking of the defensive methods adopted to counteract the effects of the gas attack, Major Dudley said that at first the casualties were very heavy among the Allied troops when the Germans made their attacks. All sorts of respirators were tried. Socks filled with damp earth, even wet handkerchiefs were tried, but, of course, did not prove effective. An appeal made to the women of England and France eventually resulted in the manufacture of the first crude respirators, mere bandages of various fabrics which the troops were instructed to dip before an attack in pails of chemicals. Later other designs of helmets were provided. The second official type was provided with mica windows and contained a bag filled with hypo sodium chlorate.

It soon became evident that this respirator was no protection against phosgen. A flannelette helmet was then devised, made of two layers of flannelette soaked in a solution of sodium phenate. In devising this helmet an important step was taken in the development of the respirator for this type first made use of the expiration valve. This was a great step forward, as by providing for the expulsion from the helmet of the carbon dioxide it prevented the carbonization of the chemical in which the helmets were soaked. It further permitted the helmet to be kept full of clean pure air at all times. It was, therefore, much cooler and comfortable than anything devised to that date.

This respirator had by various steps evolved into the present type of box respirator. In this respirator the poisonous gas was taken up by the contents, charcoal and an alkaline granule, of the box.

The box type of respirator, the speaker said, had two lines of defense. If the face piece was torn, the wearer could, of course, be effected by tear gas, but as his hose was clipped off his lungs were protected.

Charles E. Sholes, chairman of the New York Section, occupied the chair.

To Sell Enemy Property

Early in December it is the intention of the Alien Property Custodian, A. Mitchell Palmer, to sell stock in American German-owned corporations to the extent of $100,000,000.

These sales, which will be supervised by Joseph F. Guffey, Director of Sales of the Alien Property Custodian's Department, will include the sale of the following chemical and color companies.

The Bayer Company, New York City, December 3.
Synthetic Patents Company, New York City, December 3.
International Ultramarine Company, Ltd., New York City, December 9.
Heyden Chemical Works, Garfield, N. J., December 11.
New Brunswick Chemical Company, New Brunswick, N. J., December 18.
Bauer Chemical Company, New York City.

The Bayer Company and its products are very well known in America. It was owned by the Bayer Chemical Company of Germany. The Heyden Chemical Company formed a link in the plan of Dr. Hugo Schmidt to corner the carbolic acid market in this country and prevent the allied governments obtaining picric acid. This company was owned by the Chemische Frabrik von Heyden of Redebeul, Germany.

Britain Prepared for Reconstruction

Council for Scientific and Industrial Research Report Indicates Progress Made

LONDON.—While continuing to carry on their war activities with their accustomed vigor, British chemists and chemical organizations are at present, with signs of peace looming larger on the horizon daily, devoting not a little thought to the part which they are to play in connection with the solution of the problems which will face Great Britain at the close of the war. Among chemists the opinion is very widely held that in the industrial reconstruction that is to take place, the chemist must be given a proper and an adequate place.

As was pointed out at a recent meeting of the British Association of Chemists at Birmingham provision has been made by the Minister of Reconstruction that the employers and the workmen in the various chemical industries be systematically consulted in regard to the reconstruction proposals, but so far no effort had been made to provide the chemists of the country with a similar method of expression.

This ignoring of the industrial chemist to a great extent on the part of the Ministry of Reconstruction is no doubt due to lack of organization at present existing among the chemists of the country, as Prof. Hinchley pointed at a recent meeting of the British Association of Chemists. For while there are a number of associations of chemists organized for the purpose of educational work, there are few, if any, which aim to represent the political and economic interests of chemists as a profession.

When such an association is formed, it seems likely that one of the principal problems it will be called upon to handle will be the question of more adequate compensation for industrial chemists. Chemists in all parts of the world are notoriously underpaid, when the value of their work to industry is considered, and Great Britain is no exception to this rule.

The third annual report of the Committee of the Priory Council for Scientific and Industrial Research reveals the fact that a great deal of progress has been made in all parts of the country in organizing research. According to the report some thirty industries are doing preliminary work with this object. The woolen and worsted industries, the photographic industries, the Portland cement and the scientific instrument industries have already formed research associations, while a number of other equally important industries are rapidly bringing similar associations to completion.

While this report serves to indicate the high degree of progress made, it is distinctly pointed out that research organization has not yet reached that point where it is possible for information to be communicated from industry to industry. .

In summing up the result of its work during the year just past the council touches upon certain conclusions reached as a result of their efforts to organize research work which should prove of interest to American chemists and chemical organizations.

It is pointed out first that in attempting to organize research associations it is only possible to make any degree of progress when the members of an industry are conscious that there are a number of problems common to them all, the solution of which would be to their mutual benefit. As an illustration of what is meant by this rule, the Council instances its failure to organize the makers of all types of internal combustion engines. Similarly not much success has been experienced in the Council's attempts to organize the manufacturers of and users of refractories.

The Council seems convinced that attempts to form industrial research organizations can be attempted with any hope of success under certain fixed conditions only, conditions which take into consideration the peculiar problems of the various industries, and the peculiar circumstances which govern the conduct of each.

In bringing its report to a close the Council emphasises the need for an increased supply of research workers. The industries of the country must look to the educational system for these, the report points out, and therefore hearty commendation is expressed for the decisions recently arrived at by the committee appointed to inquire into the position of natural science in the educational system of Great Britain.

The recent reports emanating from German sources regarding the extent to which post war textile problems will be solved so far as Germany is concerned by the manufacture of cellulose yarns, are regarded with considerable scepticism among British textile chemists. While it is more or less generally acknowledged that the reports of the progress German chemists have made in the production of wool and cotton substitutes are very interesting, definite expression of opinion regarding the possibility of these new fibres replacing cotton and wool to any great extent is withheld until the cost of production is made known.

The Salters Company of London has formed the Salters Institute of Industrial Chemistry to provide research in industrial chemistry. It is the intention of the director of the new institute to make arrangements between manufacturers, universities and students for the investigation of any problems needing research and give practical advice to those intending to follow the career of industrial chemists.

Cross Index of Chemical Terms

Compiled by E. R. Darling

Second Instalment

THIS cross-index was prepared as an aid in finding true chemical names and other synonyms associated with them.

Chloride of Lime—See Calcium Hypochlorite.
Chrome Green—See Chromium Trioxide.
Chrome Yellow—See Lead Chromate.
Chromic Acid—See Chromium Trioxide.
Chromic Anhydride—See Chromium Trioxide.
Cinnabar—See Cobalt Oxide.
Common Alum—See Aluminum Sulfate.
Common Salt—See Sodium Chloride.
Concentrated Alum—See Aluminum Sulfate.
Constant White—See Barium Sulfate.
Coppras—See Ferrous Sulfate.
Crocosite—eSe Lead Chromate.
Corundum—See Aluminum Oxide.
Corrosive Sublimate—See Mercuric Chloride.
Cosmetic Bismuth—See Basic Bismuth Chloride.
Cream of Tartar—See Potassium Bitartrate.
Cremor Tartari—See Potassium Bitartrate.
Crocus of Antimony—See Antimony Sulfide.
Crocus Ferri—See Ferric Oxide.
Crocus Martis—See Ferric Oxide.
Crude Antimony—See Antimony Sulfide.
Crystal Carbonate—See Sodium Carbonate.
Cube Alum—See Aluminum Potassium Sulfate.
Cubic Nitre—See Sodium Nitrate.
Diacetate of Lime—See Calcium Acetate.
Diarsenious Disculfide—See Arsenic Disculfide.
Diaspori—See Aluminum Hydrate.
Diasotizing Salts—See Sodium Nitrate.
Diuretic Salts—See Potassium Acetate.
Deuto-joduretum Hydrargyri—See Mercuric Iodide.
Dried Alum—See Dried Potassium Aluminum Sulfate.
Electrolytic Salts—See Nickel Sulfate.
Emetic Tartar—See Antimony Potassium Tartrate.
English White—See Calcium Carbonate.
Epsom Salts—See Magnesium Sulfate.
Ethiop's Salts—See Mercury Sulfide.
Exsiccated Alum—See Dried Potassium Sulfate.
Factitious Cinnabar—See Mercuric Sulfide.
Febrigufe Salt—See Potassium Chloride.
Ferris Rubigo—See Ferric Oxide.
Ferrugo—See Ferric Oxide.
Fixed Mineral Alkali—See Sodium Carbonate.
Flake Lead—See Lead Carbonate.
Flake White—See Basic Bismuth Nitrate.
Flowers of Antimony—See Antimony Trioxide.
Flowers of Arsenic—See Arsenious Oxide.
Flowers of Zinc—See Zinc Oxide.
Fluid—Gelatine—See Aluminum Acetate.
Fluor Spar—See Calcium Fluoride
Fuming Liquor of Arsenic—See Arsenic Chloride
Gibbsite—See Aluminum Hydrate.
Glass of Antimony—See Antimony Sulfide.
Clauber's Salt—See Sodium Sulfate.
Golden Sulferet of Antimony—See Antimony Pentasulfide.
Goulard's Powder—See Lead Acetate.
Gray Antimony—See Antimony Sulfide.
Gray Oxide of Cobalt—See Cobalt Xxide.
Greenockite—See Cadmium Sulfide.
Green Vitrol—See Ferrous Sulfate.
Gypsum—See Calcium Sulfate.
Haheman's Mercury—See Ammonium Mercurous Chloride.
eavy Magnesia—See Magnesium Oxide.
Heavy Spar—See Barium Sulfate.
Heavy White—See Barium Sulfate.
Hepar Sulfar—See Potassium Sulfide.
Horn Lead—See Lead Chloride.
orn Silver—See Silver Chloride.
Hydrate of Baryta—See Barium Hydrate.
Hydrargyri Praecipitatus Alum—See Ammonium Mercuric Chloride.
Hydrargyri Supermurias—See Mercuric Chloride.
Hydrargyri Permurias—See Mercuric Chloride.
Hydrargillite—See Aluminum Hydrate.
Hydrosodic Cardonate—See Sodium Bicarbonate.
Hypantimonious Acid—See Antimony Trioxide.
Hypo—See Sodium Thiosulfate.
Hyposulfite of Soda—See Sodium Thiosulfate.
Indian Red—See Ferric Oxide.
Infusible White Precipitate—See Ammonium Mercuric Chloride.
Iron Chloride—See Ferric Chloride.
Iron Rust—See Ferric Oxide.
Iron Suboxide—See Ferrous Oxide.
Iron Vitrol—See Ferrous Sulfate.
Jaune Brilliant—See Cadminum Sulfide.
Jeweler's Rouge—See Ferric Oxide.
Kali Preaparatum—See Potassium Carbonate.
Kieserite—See Magnesium Sulfate.
King's Gold—See Arsenic Trisulfide.
Knig's Yellow—See Arsenic Trisulfide.
Lapis Caustic—See Silver Nitrate.
Lead Spar—See Lead Carbonate.
Light Magnesium Calcined—See Magnesium Oxide.
Lemon Chrome—See Barium Chromate.
Leipzic Yellow—See Lead Chromate.
Lime—See Calcium Oxide.
Limstone—See Calcium Carbonate.
Lime Water—See Calcium Hydroxide.
Liver of Antimony—See Antimony Sulfide.
Liver of Sulfur—See Potassium Sulfide.
Luna Casutic—See Silver Nitrate.
Magnesia—See Magnesium Oxide.
Magnesia Ponderosa—See Magnesium Oxide.
Magnesium Alba—See Magnesium Carbonate.
Manganese Vitriolata—See Manganese Sulfate.
Massicot—See Lead Oxide.

(Continued on page 462)

Method of Chromic Oxide Determination

Government Chemists Claim That New Method Permits Rapid Handling of Ore Samples Submitted for Analysis—Allows Forty Determinations in Eight Hour Day.

By W. C. RIDDELL and ESTHER KITTREDGE[*]

THE method described below was developed for the rapid determination of chromic oxide in ores and mill production submitted for analysis in connection with the War Minerals Investigation, being conducted by the U. S. Bureau of Mines. No particular originality is claimed for the method. The procedure has, however, been carefully standardized and experimental data has been obtained with respect to several important factors which may affect the accuracy of the method.

The ore should be ground to about 100 mesh. Weigh out 0.5 grams and brush into a 20 cc spun iron crucible in which has previously been placed 4 to 5 grams of sodium peroxide. Mix thoroughly by stirring the charge with a glass rod, cover with a little sodium peroxide and fuse at a red heat. After the charge has melted, it should remain in the molten condition for approximately five minutes. Allow the crucible to partially cool, place in a 400 to 600 cc beaker of pyrex or other low expansion glass, add about 100 cc of water and digest until the fused mass has disintegrated, after which remove and rinse the crucible. Boil for at least five minutes to decompose the sodium peroxide. Without filtering neutralize the solution with ¼ sulfuric acid and add 25 to 30 cc excess. Dilute to 300 to 400 cc with cold water and titrate with a standard solution (about O.2N) of ferrous sulfate. A slight excess of the ferrous sulfate solution is added, as indicated by spot plate tests with a weak solution of potassium ferricyanide (about ½ per cent. solution) and the determination is finished by back titration with standard potassium dichromate solution. The ferrous sulfate solution may be added rapidly without great care, as the approximate end point is quite easily recognized by the color change of the solution. With some practice 3 or 4 spot tests should be sufficient to determine the exact end point.

The quicknes of the method is due largely to the omission of filtration before acidifying the solution, and to the use of a standard $FeSO_4$ solution. One determination requires about two hours and a set of 10 can easily be run simultaneously by one operator. This corresponds to about 40 determinations in an eight-hour day.

Contrary to the statement found generally in the text books extreme fine grinding is not essential. Reduction to 100 mesh is ample for all purposes as is shown by the following analysis of three samples of ore which were submitted to the standard procedure except in the matter of grinding.

	%Cr_2O_3 Found		
	Sample 1,	Sample 2,	Sample 3
Ground to pass 80 mesh	49.6	35.4	53.8
" " " 100 "	49.6	35.4	54.3
" " " 200 "	49.8	35.4	54.1

Decomposition of Sample.

Chromite which is more difficult to decompose than the minerals usually associated with it yields readily to fusion with Na_2O_2. The so-called "technical" grade of Na_2O_2 may be used. A spun iron crucible is usually employed and will last for five or six melts. If care is exercised the failure of the crucible does not necessarily mean losing the charge and in some 200 determinations only two fusions have been lost in this laboratory. When iron as well as chromium is to be determined in the sample a heavy 20 cc porcelain crucible should be used. These crucibles will usually stand three or four fusions. An electric or other type of muffle furnace held at low red heat is preferred for making the fusion. The bottom of the muffle should be protected by a thick sheet of asbestos board or transite. The charged crucibles may be placed at once in the hot muffle without danger of spattering, and covers are unnecessary. When the fusion is made over a burner, the crucible should be covered and considerable care exercised to avoid spattering.

The following experiments were made to determine the time required for the complete decomposition of the chromite by fusion with Na_2O_2. All samples were ground to pass 100 mesh, and except for the time of fusion submitted to the standard procedure.

	%Cr_2O_3 Found		
	Sample 1	Sample 2	Sample 3
Heated until just melted	49.6	35.1	54.0
Fused 2 min. after melt.	49.8	35.4	55.0
" 5 " " "	49.9	35.4	55.1
" 10 " " "	49.8	35.4	55.1

From these results it is evident that it is amply sufficient to hold the charge in a molten condition for five minutes.

Not only during this phase of the new method is it possible to reduce very materially the time necessary for the making of tests, but as will be shown by the account of experiments which follows, a similar reduction can be made throughout.

The following experiments which were identical except as regards time of boiling, indicate that five minutes is sufficient to decompose the H_2O_2 (formed by reaction of Na_2O_2 with H_2O) in solution.

---

[*] *Published by permission Director United States Bureau of Mines.*

	$\%Cr_2O_3$ Found		
	Sample 1	Sample 2	Sample 3
Acid added without boiling	—	48.1	54.0
Heated just to boiling	14.8	49.3	55.1
Boiled for 5 min.	14.9	49.4	55.3
Boiled for 10 min.	15.0	49.3	55.2

If any H_2O_2 is present in the solution when the H_2SO_4 is added, some chromate will be decomposed leading to a low result.

The alkaline solution containing the precipitate inclines to bump on boiling. A few chips of fresh unglazed porcelain or a solid stirring rod with a roughened end placed opposite one of the points where the beaker makes contact with the hot plate, minimized this difficulty.

Non-removal of Precipitate.

The quickness of the method is partly due to avoiding the tedious filtration of the alkaline solution. Except when manganese is present, filtration is unnecessary as is shown by the following parallel determination on a number of samples.

Solution acidified without filtration	Solution filtered before acidifying	In precipitate
38.5	38.6	—
40.4	40.0	0.3
56.4	55.7	—
49.3	49.1	0.2
53.8	55.3	0.3
55.2	55.0	—
55.8	55.6	—
55.7	55.4	0.2

In certain cases the precipitate after considerable washing was dissolved in acid. This solution was then made alkaline, the precipitate removed by filtration, and the chromium determined in the filtrate. These experiments show that it is quite difficult to completely remove the chromate from the bulky gelatinous precipitate. The short procedure which we have adopted is therefore the more accurate unless interfering substances are present.

Interfering Elements.

Determinations were made in which small quantities of cobalt, nickel and copper salts were added to known samples before starting the analysis. These additions did not influence the result.

Manganese is the only interfering element which is at all likely to be found associated with chromite. When this is present it will appear in the form of hydrated di-oxide as a brown gelatinous precipitate after the solution has been acidified. In this case filtration is necessary. Filtration may be considerably facilitated by the addition of mascerated filter paper.

The standard $FeSO_4$ solution should be about 0.2 normal. This solution is prepared by dissolving 56 to 60 grams $FeSO_4 \cdot 7H_2O$ in about 800 cc distilled water to which has been added 100 cc concentrated H_2SO_4. The heat generated by the addition of the H_2SO_4 readily effects the solution of the ferrous sulfate. After cooling the solution is diluted to one liter. The 0.2 normal K_2Cr_2O7 solution may be made by dissolving 9.806 grams C.P. K_2Cr_2O7 in one liter. The $FeSO_4$ solution may be standardized with a standard $KMnO_4$ solution based on Bureau of Standards sodium oxalate, or against the K_2Cr_2O7 solution, provide this was made from a salt of known purity. The $FeSO_4$ solution acidified as suggested is quite stable and if properly protected requires checking against the standard K_2Cr_2O7 solution only two or three times a week.

One cubic centimeter of 0.1 normal solution is equivalent to 0.001733 grams Cr, or 0.002532 grams Cr_2O_3.

CROSS INDEX OF TERMS

(Continued from page 460)

Marble—See Calcium Carbonate.
Melaconite—See Cupric Oxide.
Metallum Album—See Arsenious Oxide.
Milk of Barium—See Barium Hydroxide.
Mineral Butter—See Antimony Chloride.
Mordant Salts—See Potassium Antimony Tartrate.
Muriate of Aluminum—See Aluminum Chloride.
Muriate of Antimony—See Antimony Chloride.
Muriate of Arsenic—See Arsenic Chloride.
Muriate of Cadmium—See Cadmium Chloride.
Muriate of Calcium—See Calcium Chloride.
Muriate of Cobalt—See Cobalt Chloride.
Muriate of Copper—See Copper Chloride.
Muriate of Iron—See Iron Chloride.
Muriate of Lead—See Lead Chloride.
Muriate of Lime—See Calcium Chloride.
Muriate of Manganese—See Manganese Chloride.
Muriate of Mercury—See Mercuric Chloride.
Muriate of Silver—See Silver Chloride.
Muriate of Soda—See Sodium Chloride.
Muriate of Zinc—See Zinc Chloride.
Natron—See Sodium Carbonate.
Natron Vitrolate—See Sodium Sulfate.
Natrun—See Sodium Carbonate.
Neutral Sulfate of Alum—See Aluminum Sulfate.
Nickel Black—See Nickel Oxide.
Nigri Precipitatus—See Ammonium Mercurous Chloride.
Nil Alba—See Zinc Oxide.
Nil Album—See Zinc Oxide.
Nitre—See Potassium Nitrate.

(To be concluded.)

A charter has been granted to the Sanitary Flooring Co., Inc., Manhattan. The authorized capital of the company is $25,000. The incorporators are J. B. Cheney, 51 West 21st Street, New York City; C. H. Pardoe, Washington, D. C., and L. R. Lord, 609 West 137th Street, New York City.

To manufacture drugs, chemicals and medicines, the Partola Distributing Company has been incorporated under the laws of the State of New York with an authorized capital of $95,000. S. A. Clarkson, 1566 East 13th Street; F. F. Carroll, 256 Warren Street, and A. M. Hicks, 543 Ninth Street, Brooklyn, are the incorporators

Potash Situation Growing Serious

United States Still Unable to Provide Her Own Full Requirements—Output Today Approximately Twenty Per Cent. of the Country's Normal Needs.

By R. C. RANDALL

THE announcement from San Francisco early this month that another unit of the American Trona Company's plant at Searles Lake in Southern California, has started operation, served to mark another stage in the systematic efforts both Government and private agencies have been putting forth, since the outbreak of war with Germany, to make the United States independent of foreign potash sources.

The announcement is important because it serves to indicate that today most development work so far as potash is concerned is being done where it seems most likely to result in the establishment of a permanent industry—that is in the Searles Lake district.

It is also important because it offers ground for hope that in the not far distant future the American fertilizer manufacturer and the American farmer and all other industries which depend for one or other of their materials upon the potash supply will be again assured of an adequate supply at a reasonable price.

During 1913 there was imported, principally from Germany, 228,552 tons of K_2O. At the beginning of 1917 the Committee on Fertilizers of the Chemical Industry of the Chemical Alliance estimated that the country's needs in the direction of potash during the year ahead would be 218,899 tons. A summary of the estimates made by the directors of the various state agricultural stations by the Department of Mines showed that the minimum requirements during the present year would be in the neighborhood of 150,000 tons, based upon the present percentage of potash now used in fertilizers. As the present potash content of most fertilizers is universally acknowledged to be too low—the inevitable result of war conditions—and the total output during 1917 was only twenty per cent. of the minimum requirements for 1918, the situation is today serious.

Demand to Increase.

The future will see, if anything, an increased demand for potash in the United States. Conservative estimates place the demand during 1919 at 250,000 tons. According to reports by the Department of Agriculture at Washington the soil in many parts of the country, due principally to the unusual demands that have been placed on the farmers in the direction of increased production and second to the low potash content of the war time fertilizers, are giving marked evidence of "potash hunger." Experiments conducted in Maine by officials of the erate quantities of potash to the evil, doubled the output of potatoes and that the potash could not be replaced by any other ingredients. The experiments conducted here further proved that the amount of potash required by the soil conformed more or less closely to pre-war practice and proved to the satisfaction of the experimenters, that so far as truck crops, at least, were concerned, any reduction of the potash content of the fertilizers used could not help but prove injurious to the crops.

Much similar conclusions have been reached in regard to the cotton crops of the South. There is Department showed that the addition of even mod- a tendency at present among agriculturists to blame the prevalence of "rust" upon the fact that in almost every case "rust" appears only on soil deficient in potash. According to estimates made by officials of the Department of Agriculture a normal cotton crop contains about 270,000 tons of potash. The quantity of potash required for such a crop on a basis of two per cent K_2O, would require 100,000 tons of K_2O.

Soil Being Impoverished.

Ever since the flow of potash from German sources stopped with the outbreak of war in Europe, the soil of the United States has apparently been subjected to a progressive impoverishment. Strenuous efforts have been made to replace the supply which war conditions removed, by potash obtained from domestic sources but as the figures given above show, so far without entire success. From now on with the feeding of the greater part of Europe dependent upon the efforts of American farmers and the productivity of American farms, the question of an adequate potash supply becomes not only of national but of international importance.

Whether or not we can expect a return to prewar conditions so far as the importation of potash from Germany is concerned, it is of course at this early stage of the peace negotiations impossible to say. But it can be said with a fair degree of safety that even if the final peace arrangements permit of any approximation of the freedom of commercial intercourses with the ci devant Teutonic Empire which prevailed before the war, it is of course questionable whether the German supply of potash can be depended upon for some time to come, due principally to the disturbed condition of the country and the inadequacy of the available merchant marine of all countries.

It is therefore as imperative as ever that no effort be spared on the part of the Government or private enterprise to develop all possible sources of potash in the United States, because it will be upon these sources that the country will apparently have to depend for some time to come.

It is on account of this condition of things that an inventory of America's available potash resources is interesting and important.

Some appreciation of the situation in the United States can be obtained from the following table giving in detail the amount of potash obtained during 1917 from various sources:

	Tons K_2O.	Per cent. of total production
Mineral sources:		
Natural brines	20,652	63.4
Alunite	2,402	7.3
Dust from cement mills	1.621	5.0
Dust from blast furnaces	185	0.6
Organic sources:		
Kelp	3,572	10.9
Molasses residue from distillers	2,846	8.8
Wood ashes	621	1.9
Waste liquors from beet sugar refineries	369	1.1
Miscellaneous industrial wastes	305	1.0
Total	32,573	100.0

Today most of the potash produced in the United States comes from the Nebraska lakes and Searles lakes of southern California.

The Nebraska lakes are a series of small shallow lakes in the sand hill region of Nebraska, north and south of the Chicago, Burlington & Quincy Railroad, between Alliance and Lakeside. Something like seventy-five per cent. of these lakes contain sufficient potash to make the extraction commercially interesting. They contain brine of varying strength and have a bottom of muck and hardpan, beneath which is found a bed of sand from two to forty feet thick. This sand is in most cases soaked with brine of a composition similar to that in the lake above. At first the production of potash depended upon the water in the lake only but today the sands beneath are the principal source.

Worked from Wells.

Today these lakes are being worked by means of wells sunk in the lake beds. By means of a suction line the brines taken from these wells are pumped to reduction plants, where they are partly evaporated by solar towers and later in driers or in some cases in large open tanks heated by means of steam coils. Later the salts are dried in rotating furnaces, heated by the direct flame of oil burners. Before shipment the salts are dried, ground and packed in bags.

There are at present four plants turning out potash in this district, the four having a capacity of about 100,000 tons of potash salts per annum. This probably represents about 25,000 tons of K_2O.

Most of the salts being turned out in this district are being used in fertilizers. While the Nebraska salts have the advantage of a low content of chlorides, objection is made to them in some quarters on account of their alklinity. This the chemists of some of the fertilizer companies claim prevents their use in anything but the low grade fertilizers at present being used.

According to competent opinion * the Nebraska lakes cannot be considered as a permanent source of supply. When the plants now operating and those under construction and contemplated are run at full capacity, it would seem that the supply of high grade brines will be reduced within a few years.

The cost of production at this point permits of potash salts on a basis of 28 per cent. K_2O, being laid down on the Atlantic seaboard at about $1.50 per unit of K_2O. The cost of production is said to be about $30 a ton.

While the Nebraska Lake district will be an important source of supply, so long as the present demand for potash continues it cannot be looked upon in the same way as the Searles Lake.

Searles Lake is a salt incrusted valley floor with an area of twelve square miles. The depth of the salt beds is from sixty to one hundred feet, averaging about seventy-five feet in the main part of the deposit. The deposit is really a mass of salts crystalized from an evaporated mother liquor brine, in which the salts are still immersed. First estimates of the contents of this deposit gave 4,000,000 tons of K_2O. But this is today considered too conservative. It seems likely that 12,000,000 tons would be nearer the correct figure.

At Searles Lake plants are being operated by the American Trona Company and the Pacific Coast Borax-Solvay Process Company. The American Trona Company, the largest producers of potash in the United States, has a concentrating plant at Trona capable of handling 4,000,000 gallons of brine a day. The brine is evaporated at the plant and concentrate shipped to a refinery at San Pedro, California. The estimated output for 1918 is 15,000 tons. This output will likely be doubled in 1919 and it is expected that eventually the total output will be close to 100,000 tons.

The Future of Searles Lake.

According to a statement made in a recent review of the situation at Searles Lake by an official of the Department of Mines, the cost of production at this plant cannot yet be definitely determined. It is likely that the cost will depend upon the quality of the output. In this review it is pointed out that the future production of this plant depends to a great extent upon the ability of the market to absorb the by-products of salt, borax and soda. This the market cannot do, it is claimed, if the plant is worked to capacity.

Next to the brines, derived from these two sources, the United States is obtaining most of its potash from alunite. The only deposits of this mineral being worked on a commercial scale are located at Maryvale, Utah. The plant of the Minerals Products Corporation at this point turns out about 20 tons a day of 97 per cent. potassium sulphate.

The process used at this mill involves the crushing of the alunite to the size of about one inch. After going through the crushers the alunite is roasted in rotary kilns, 7 feet 6 inches by 135 feet, pulverized coal being used as fuel. After calcining the material is leached with hot water in a closed tank at a temperature equivalent to a steam pressure of 60 pounds, the potassium sulphate going into solution. The solution is then sent through a filter press; the clear filtrate is evaporated in triple effect evaporators and the residue sacked.

At present no use is being made of the alumina left after the potash has been leached. No estimate of the cost of production is available but it is understood that the minimum freight rate on a high grade potassium sulphate to eastern points would probably amount to 25 cents a unit of K_2O, so that unless the alumina can be utilized in some way the opinion has been expressed that this plant cannot operate at a profit under normal peace time conditions.

A considerable quantity of calcined alunite is at present being marketed among fertilizer manufacturers as experiment has shown that this is as effective per unit of K_2O as the soluble sulphate and chloride salts. Calcined alunite will not likely due to its low content of K_2O be much in favor for this purpose when normal industrial conditions return again, because of the high freight rates involved in its transportation.

A great deal has been heard lately of the potash recovered from kiln dust produced at cement plants. While of course the supply of potash available from this source is somewhat limited the estimated cost at which it is produced, thirty to fifty cents a unit of K_2O will enable the mills to compete with the German product on the basis of pre-war products.

Discovered by Accident.

Two American cement plants have been conspicuously successful with this method of producing potash. The first, the Riverside Portland Cement Company, of California, can be credited with having discovered this method of producing potash. Threatened with numerous suits from fruit growers in the vicinity of their plant, on the ground that the dust from their mills were ruining the fruit trees, they installed an electrical dust precipitating plant to abate the dust nuisance. The dust collected by this plant when analyzed was found to contain a ten per cent. potash content. This plant has been operated ever since 1913 and has proved highly profitable.

Similar plants are being operated with equal success by other cement plants in various parts of the country. All seem to have found that not only does the production of potash involve no change in the ordinary methods of manufacturing cement but that in some cases the installation of such a dust precipitating plant leads to a reduction of as much as ten per cent. in the consumption fuel. This is due to the more careful attention required in the burning of the cement.

An investigation recently completed by the Bureau of Soils indicated that the probable maximum amount of potash that might be recovered from all the cement works in the country would be 100,000 tons of K_2O per year. It is not likely that dust collecting plants will ever be installed at all cement works, but it seems reasonable to expect that the amount of K_2O to be derived from this source should reach 50,000 tons a year, or 20 per cent. of the total normal requirements. Probably this amount could be increased somewhat by using where available rock containing more K_2O in the raw mix.

An objection raised to cement-kiln dust as a source of potash in manufacturing fertilizers is that if used in large quantities the lime content will cause reversion of the soluble phosphoric acid in the phosphate and loss of the ammonia in ammonium sulphate. The K_2O content of cement-kiln dust is also too low to permit its use as the only source of potash in a fertilizer that is to contain more than 3 per cent. of K_2O. However, these objections can easily be overcome, and some potassium sulphate containing 40 per cent. of K_2O is now being marketed by one of the cement works.

Space forbids a detailed description of the various methods of obtaining potash, which under the stimulus of the war, have been developed in the United States, but in addition to the brine lakes, alunite mines, and cement works, mention must be made of three other less well known sources, the dust from blast furnaces, the feldspars and other silicates and kelp.

The recovery of potash as a by-product of the manufacture of pig iron was first investigated at the plant of the Bethlehem Steel Company. Dust collected in the stove and furnace passes was found to contain ten percent of potash. Further investigation revealed the fact that this potash represented only a small proportion of the potash produced as over 67 percent escaped up the stacks and in the primary washers.

Two Plants Building.

A plant is now being erected at Bethlehem to collect potash from these gases and another will likely be built in Alabama. No figures regarding the total potash produced in blast furnaces are yet available.

The development of this source is regarded as very promising by those who have made a close study of the potash situation and the opinion is expressed among some engineers that with proper encouragement from the Government the combined efforts of the iron and cement industries should be able to provide the country with sufficient potash for all its needs.

The extraction of potash from feldspars and other silicates is still more or less in an experimental stage but this method of obtaining potash is believed to promise good results in the not far distant future. Deposits of greensand containing payable quantities of K_2O exist in many localities within easy reach of the centres where fertilizers are most in demand.

The kelp which grows in immense quantities off the Pacific coast has been regarded for many years as an admirable fertilizer, but it was not until the outbreak of the war and the incidental demand for potash that extensive efforts were made to make available the potash content of this sea weed.

It has been estimated that from Cape Flattery to San Diego there is sufficient kelp to furnish 250,000 to 400,000 tons of K_2O annually. This estimate is believed to overstep the mark somewhat as all of the kelp which grows on the coast, on account of the exposed position of parts of the coast line, cannot be harvested.

Several plants are now in operation on the Pacific coast and the output from this source ranked second during 1917.

The kelp is harvested by machine cutters, loaded on barges and brought to shore, and either dried and ground or reduced to a char. This product may be used either as a fertilizer or as a basis material for the production of high grade potassium chloride.

The plant of the Hercules Powder Company at this point is now producing potassium chloride 97 to 98 percent pure in substantial quantities and also acetone, iodine and ethyl products.

Summing up the future possibilities of this district in a report prepared for the Department of Mines, A. W. Stockett expresses the opinion that the permanence of the kelp potash industry depends upon the possibility of obtaining a market for the byproducts. He believes that the location of the beds and the fact that only one percent of the potash used in the United States goes West of the Rockies, limits the ability of this source to supply the needs of the Eastern States.

The same writer in summing up the whole potash situation as it exists in the United States says: "to sum up the normal requirements of the country are 250,000 tons of K_2O a year. The total production during 1917 was 32,573 tons of K_2O: the present principal sources are natural brines, kelp, molasses residue, alunite and dust from cement kilns: the most promising sources of a permanent supply sufficient for all future requirements are the natural brines from Searles Lake, dust from the cement kilns and blast furnaces, with favorable prospects from the green sand deposits."

Dr. Pickrell Favors Census

Census of Chemical Imports Most Important, He Claims.

ADVANTAGES to be derived by American chemical industries from the census of chemical imports and the methods of its preparation were discussed in a paper recently presented before the New York Section of the American Chemical Society by E. R. Pickrell. After crediting the idea of the census to Dr. Bernhard C. Hesse, Mr. Pickrell said in part:

"The census of chemical imports is a much greater and more difficult task than the dyestuff census, for it entails the procurement of information relating to a vast and varied number of articles. The statistical data presented by this census will not only be of value to chemical manufacturers but to the drug manufacturers, synthetic medicinal manufacturers, perfumery manufacturers, paint and varnish industries, oil industries and fertilizer industries.

"During the fiscal year 1913-1914, chemicals, allied chemicals, drugs and medicinals imported into this country totaled in value $176,000,000. This total was divided as follows:

Chemicals, drugs, dyes and medicines	$95,000,000
Oils	46,000,000
Fertilizers	23,000,000
Tanning materials	2,000,000
Perfumes	2,000,000
Paints	2,000,000
Glue	2,000,000
Grease and oils	1,000,000
Soap	1,000,000
Oleostearine, dyewoods, beeswax and blood (each)	500,000

"Inasmuch as the object of the Census of Chemical Imports was to show the quantity, value, country of origin, and per cent. of the quantity imported from each foreign country of every chemical, drug, allied chemical and medicinal imported into this country for the fiscal year 1913-1914, the last normal year, and since there was no available statistical data in this country setting forth this information, it was necessary to examine every invoice filed at the different custom houses in this country during that one fiscal year.

"In view of the fact that more than sixty per cent. of all the articles imported into the United States come through the port of New York and that probably seventy-five per cent. of all the chemicals imported are entered here, it was deemed advisable that the clerical staff engaged on the census personally examine the New York entries.

"The original request was made to the Secretary of the Treasury that all invoices, some 700,000 received in the United States for the fiscal year 1913-1914, be forwarded to the Port of New York for examination by the staff engaged in the census.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS*

Part XIX

In addition to the narrow group of bands between $\lambda = 270$ and 230 $\mu\mu$, according to *Stark* and *Levey* (Jahrb. Radiaokitv. Elektronik. 1913, 10, 179; J. Chem. Soc. 1913, Abs. *104*, ii, 366) the absorption spectrum of benzene shows a much more intense group of similar bands in the region $\lambda = 210$ to $\lambda = 190$ $\mu\mu$. Naphthalene behaves in the same way, a group of narrow intense bands being found in the region $\lambda = 220$ to $\lambda = 190$ $\mu\mu$ in addition to the less intense group situated between $\lambda = 310$ and $\lambda = 230$ $\mu\mu$. Both the naphthalene bands are displaced towards the direction of greater wave-lengths relatively to the corresponding benzene bands. The absorption spectra of cyclohexene and Δ 1:3—cyclohexadiene, on the other hand, exhibit unresolved broad bands differing completely from the groups of narrow bands shown by benzene and napthalene. From the totally different character of the benzene bands as compared with those of cyclohexene and ∇ 1:3—cyclohexadiene, the conclusion is drawn that the benzene ring contains no normal ethylene linkings. Reference is made to the fact that the observed molecular refractivity of benzene agrees with that calculated on the assumption that benzene contains three normal linkings. This agreement does not, however justify the conclusion that three such linkings are present. According to Stark and Levey, the ultra violet absorption of benzene would seem to show that agreement is accidental and due to the circumstances that the refractivities of the actual linkings are mutually affected by their close approximation (as in the case of conjugated ethylene linkings), and that the modified refractivity is practically equal to the refractivity of a normal ethylene linking.

Former investigators having made reference to the irregular band spectrum of p-xylene in the ultra violet, *Mies* (Zeitsch. wiss. Photograph. Photophysik. Photochem., 1909, 7, 357) investigated the absorption in the ultra violet of p-xylene vapor and also of solutions of p-xylene in alcohol. In no case is there an alteration in the selective absorption. Neither temperature, nor thickness of the absorbing layer nor pressure have an influence on the heads of the bands. There is not any evidence of the broadening of the bands. With a constant thickness of the absorbing layer, rise in temperature appears to increase the intensity of the heads of the bands of the longest waves. The general absorption increased with the temperature and with the thickness of the absorbing layer. It is most marked toward the red end of the spectrum, and gradually increases in the direction of the shorter wave-length, until at $\lambda = 2389$ it becomes zero. The spectrum is a very pronounced band spectrum, in which the individual bands are not resolved. All the bands have their edges toward the violet, and become diffused towards the red.

In order to ascertain the influence of the relative position of the methyl groups on the ultra violet absorption spectrum *Mies* (Zeitsch. wiss. Photochem., 1910, 8, 287; J. Chem. Soc., 1910, Abs., *98*, ll, 563) has investigated the vapors of o- and m-xylene by the same method as that previously used for p-xylene. The absorption of m-xylene is considerably weaker than that of the p-compound, and contains only one series of bands instead of the two exhibited by p-xylene. The absorption of o-xylene is still smaller. The relative behavior of the three xylenes in the liquid state is similar to that found by the examination of the vapors.

Ethyl Benzene.

The absorption spectrum of ethyl benzene in the ultra violet has been examined by *Weimer* (Zeitsch. wiss. Photochem., 1913, *12*, 33) over the interval $\lambda = 2300$ to $\lambda = 2750$, observations being made on the vapor at temperatures between 20° and 80°, and on ethyl alcohol solutions containing from 0.02 to 50% of ethyl benzene. In both cases, the spectrum consists of a series of bands which are shaded off towards the red end of the spectrum. With rise of temperature the vapor bands broaden out towards the red end, but the short-waved edges of the band are unaltered in position by either change of temperature or of the thickness of the vapor column. In the case of the solution spectrum, on the other hand, it is found that the bands are displaced towards the red as the concentration is increased. On comparing the ethyl benzene spectrum with that of toluene, it is seen that the two are identical except for the fact that the former is displaced towards the ultra violet to the extent of 0.7 $\mu\mu$.

MISCELLANEOUS HYDROCARBONS.

A large number of hydrocarbons have been examined by *Stark, Steubing, Enklaar* and *Lipp* (Jahrb. Radioaktiv. Elektronik., 1913, 10, 139; J. Chem. Soc., 1913, Abs., *104*, ii, 363) with reference to their behaviour towards ultra violet rays of short wave-length. By means of a fluorspar spectrograph, it has been possible to obtain satisfactory photographic records of the absorption spectrum as far as $\lambda = 185$ $\mu\mu$, and in this way the region covered by previous investigators has been considerably extended. The hydrocarbons were examined in the form of vapor, the rays being caused to pass through a layer of constant thickness, while the pressure was reduced in a series of steps in order to obtain the spectrum for different concentrations. The experimental observations are interpreted in accordance with the view that the absorption of ultra violet light is a specific property of the carbon atom. The seat of the absorption is supposed to be the valency electron, and the position of the obsorption band is further supposed to depend on the linking with which the valency electron in question is associated.

---

* All rights of publication in book form reserved by the authors. Consulting Chemists and Chemical Engineers, 92-98 Greenwood Ave., Montclair, N. J.

The experimental data indicate that the linkings C—H and C—C do not give rise to an absorption band at wave-lengths greater than λ 185 $\mu\mu$; bands are found in this region, however, in the case of the linkings C=C and C≡C. Hydrocarbons which contain asymmetric double linkings or triple linkings give rise to two broad bands and it may, therefore, be supposed that the four or six valencies associated with the C=C and C≡C linkings respectively are approximately equivalent as regards their ultra violet absorption, and the bands may, therefore, be regarded as peculiar to the linkings as a whole. The presence of two or more C=C or C≡C linkings in the molecule of a substance has an appreciable influence on the position as well as the intensity of the absorption, and the nature of these effects is indicated by the curve for different classes of hydrocarbons. The data for hexane, cyclohexane, camphane indicate that the C—C linking, whether in an acyclic or a cyclic compound, does not give rise to selective absorption above λ 185 $\mu\mu$. Although the absorptions do not show a fully developed band, it would appear that ring formation causes a shift towards the long-waved region. These results show that the carbon valency associated with an asymmetric C=C linking, whether in a cyclic or an acylic compound, gives rise to two broad bands in the ultra violet region above λ 180 $\mu\mu$. As compared with the position of the bands due to a single C=C linking, it appears that the bands are displaced towards greater wave-lengths, and at the same time intensified, if the C=C linking is endo- or semi-cyclic, or if the linking is conjugated with reference to a second C=C linking.

Other compounds examined were isobutylene, methyl butylene, hexylene, octylene, diallyl, geraniolene, methyl butadiene, dimethyl butadiene, methyl pentadiene, hexadiene, camphene, bornylene, pinene, limonene sylvesterene, phellandrene dimethyl fulvene and ethylene. Liquid ethylene was found to absorb ultra violet rays up to λ 235 $\mu\mu$.

Pauer (Chem. Centr., 1896, i, 1122; Ber. Physikal. Med. Soc. Erlangen, *27*, 120; J. Chem. Soc. 1897, Abs. *72*, ii, 393) examined benzene, toluene, the xylenes, ethylbenzene, chloro-, bromo-, iodo-, nitro-, amido-, azo-, and amidoazo-benzene; carbon bisulphide pyridine, thiophene, anthracene, and naphthalene to determine their absorption spectro in the ultra violet. All the compounds in the liquid state or in solutions of suitable concentration give rise to absorption bands near the cadmium lines 17—20. The absorption spectra of the same substance in solution in different solvents show a displacement towards the red which increases with the refractive index or the dispersion of the solvent. The absorption spectra of the vapours consist of lines, or groups of line, which form one or more bands as the substance passes from the gaseous to the liquid state. The position of the bands for the liquid is always nearer the red than that of the lines or groups of lines, for the vapour.

The influence of constitution on the absorption in the case of the benzene derivatives was not found to follow any regular course. The character of the absorption alters entirely with the substitution of different hydrogen atoms. Nitro-benzene and iodo-benzene in the gaseous state, he states, give rise to no lines whatever. Benzene, naphthalene, and anthracene in solution each give four bands, which lie nearer to the red the greater the molecular weight of the compound. The substitution of N and CH entirely alters the character of the benzene spectrum. The absorption in the case of benzene is very intense, so that even traces of the vapour of the former in admixture with air could not be detected.

The ultra violet absorption spectrum of the vapors of a number of mono-substituted derivatives of benzene has been examined by *Strasser* (Zeitsch. wiss. Photochem., 1915, 14, 281; J. Chem. Soc., 1915, Abs., *108*, ii, 499). The wave-length data for the absorption bands exhibited by benzaldehyde, benzonitrile, benzyl alcohol, benzyl ethyl ether, and benzoic acid show that the spectra of these derivatives are similarly constituted.

Purvis (Proc. Camb. Phil. Soc. 1909, 15, 89) has also compared the absorption spectra of mesitylene and trichloromesitylene in 0.001 molar ethyl-alcholic solution. By the introduction of the three chlorine atoms the strong absorption band is shifted towards the red from λ 269 — λ 254 to λ 287 — λ 263 $\mu\mu$. The persistence of the latter is very much greater than that of the mesitylene band.

The influence of substitution in the benzene nucleus on the nature of the light absorption has been further examined by *Purvis* (J. Chem. Soc. Trans. 1015, 106, 660) by comparative observations on the absorption of anisole, p—bromoanisole, phenetole, p—flourophenetole, p—bromophenetole, o— and p— anisidines, o— and p—phenetidines, p—azoxyanisole and p—azoxyphenetole. The results obtained with anisole and phenetole show that the introduction of an aliphatic group does not alter the character of the absorption, although the bands are not so sharp as those of phenol. When fluorine or bromine is introduced in the nucleus

Should Nationalize Color Trade

President National Aniline and Chemical Company Claims U. S. Should Take Step.

AT the recent manufacturing conference of the the National Aniline & Chemical Company, Inc., held at Buffalo, Mr. William J. Matheson, president of the company, speaking of the future of the color business, emphasized the immediate necessity of nationalizing the color industry in the United States as was done in other important civilized countries.

"Germany nationalized the color industry there long before the war; France has now nationalized it; Japan has nationalized it; Great Britain has nationalized it; and it is absolutely essential that the United States should do so.

"We must divorce our minds from the situation that prevailed before the war. The very fact that Germany united all works under one system for their own protection leaves this country no alternative. France has met this situation; Great Britain has met it; Japan has met it; and this country must meet it."

Mr. Matheson said that there was no doubt but that Germany had sold some goods below the cost of manufacture, when a discontinuance of manufacture would tend to disorganize the whole plant of Germany; or where it would operate to put American companies out of business. The German manufacturers operated together and distributed the loss over all. They stated quite frankly that they did not think it advisable to allow this industry to become profitable in the United States. The price was never predicated on what the product cost, but on how much it would bear. He emphasized the fact that years before the war, when six big companies were operating in two groups, the German dye manufacturers were "competing under control."

Over $3,000 has been contributed to the Ramsay Memorial Fund in the United States up to November 1. It is hoped that the American subscription may reach $10,000 by January 1, 1919. Checks should be made payable and sent to the Ramsay Memorial Fund Committee. W. J. Matheson, Treasurer, No. 2 Burling Slip. New York City.

Temperature Factor in Silk Dyeing

Dynamite Bath Should Not Be Over Sixty Degrees.

The preservation of silk during its passage through the dye-house is of vital importance. Few dyers thoroughly understand the necessity of guarding it against every possible attack by either mechanical or chemical influences, according to the American Silk Journal.

One of the most essential points is the temperature of the dynamite bath, which should on no account be permitted to rise above 60 degrees Fahrenheit. Silk immersed in a dynamite bath having a higher temperature than 60 degrees Fahrenheit, becomes tender, and when once attacked, there is no possible chance of restoring its strength. To keep the dynamite bath properly cooled, the use of ice water is necessary.

A double-walled lead-lined tank, to permit cold water to circulate, is excellent, or a cooling coil of lead pipe around the inside of the tank is better. Generally, stone crocks, one at each end of the tank, will suffice. They should be large enough to contain about 75 to 100 pounds of ice when broken into fragments.

Before putting the silk into the tin, the thermometer should be used, and if the temperature of the liquor is much above 60 degrees Fahrenheit, the use of a fair-sized chunk of ice directly in the tin will soon lower the temperature, without materially altering the density of the bath. As soon as the proper temperature is obtained, the ice is removed from the liquor and put in one of the crocks. It is a good silk insurance to keep a thermometer near the tin liquor and to insist upon its use, especially in summer time.

R. N. Ball, Jr., has been appointed assistant manager of the New York Oil Department of Marden, Orth & Hastings Corporation. Mr. Ball was formerly associated with this same department before his transfer to the Chicago office of the same corporation.

H. L. Wraight, 1016 Woolworth Building, has been appointed New York representative of the American Nitrogen Products Co., a Washington corporation.

A chemical for preserving art objects has been devised by Dr. Chikashige, of the Kyoto University, according to the Japan Times. The chemical is said to have proved very effective as a preservative of pictures

United States to Be Independent

Chairman of War Industries Board Says War Will Free Chemical Industries

Bernard M. Baruch, chairman of the War Industries Board, believes that shortly America will be independent of the rest of the world, in so far as the chemical and mineral products hitherto obtained from Germany are concerned. The chemical division of the War Industries Board, according to Mr. Baruch under the capable guidance of Charles H. L. McDowell, has met with considerable success in the development of new processes of manufacture and in the manufacture of materials hitherto protected by German patents. So far they have succeeded in inducing American manufacturers to make soluble potash, aniline dyes, optical glass and clay for graphite chemicals of German origin.

In spite of the fact that the food administration recently recommended the use of saccharin as a substitute for cane sugar, the Secretary of Agriculture declares that he will regard any food product in which saccharin has been substituted for cane sugar, as adulterated, under the terms of the Food and Drug Act. Saccharin, according to the Department, impairs digestion when used in quantities over three-tenths of a gram a day and deduces the food value of the substance in which it is used.

Secretary of Commerce William C. Redfield in the course of a plea for the continuance of good will advertising on the part of American exporters, cites the exhibitors at the recent Fourth Exposition of Chemical Industries, in support of his belief that good will advertising should continue in spite of the war and in spite of the fact that few if any manufacturers are in a position to supply goods for export.

"Let me suggest good will advertising for all firms that have no reason to expect improvements in their foreign business while hostilities continue," says the Secretary. "Such advertising does not aim at immediate results. It is intended to keep the name of the firm or of a product before a community when conditions have interfered with actual trading.

"I think the most noteworthy feature of the recent Chemical Exposition in New York was the fact that of all the exhibitors only a very small percentage were looking for orders or could possibly fill orders if they found them. They are devoting all their manufacturing efforts to war purposes, but are giving a reasonable amount of attention to keeping their goods and their marks before their prospective future customers. That is one sort of good will advertising."

A new explosive known as nitrobyronel, the invention of Dr. Byron E. Eldred, is being tested by the Government. It is claimed that this new material blows a chamber twice the size of that blown by trinitrotoluol. As neither nitroglycerin or toluol is used in the manufacture of nitrobyronel, it is believed that a big saving of glycerin can be affected by the use of the new explosive as a substitute.

Secretary of Agriculture Houston has appointed an advisory board to devise methods of drying fruits and vegetables, consisting of representatives of each of the bureaus within the Department of Agriculture. The board will have charge of the growing dehydrating industry of the country.

Dr. Arthur L. Day has resigned as director of the Geophysical Laboratory, Carnegie Institution of Washington, to do research work for the Corning Glass Works, Corning, N. Y.

Chemical Personalities

Lloyd Atkinson Leaves Air Reduction Company—George Chahoon in Baltimore

Lloyd H. Atkinson has resigned as vice-president of the Air Reduction Company, Incorporated, 120 Broadway, New York City. Mr. Atkinson has been in poor health for some time, as result of overwork, and will take an extended vacation before engaging in one of the war service activities.

Mr. George Chahoon, president of the Laurentide Company, is now located in Baltimore, where he is attached to the welfare branch of the Chemical Warfare Service. Mr. Chahoon's services have been loaned by the company to the Government for the duration of the war.

Mr. Lucius Allen, of Bellville, Ont., Canada, has been appointed consulting chemist to the Nitrate Division of the Ordnance Department with the rank of captain.

Dr. Donald Kohr was recently appointed assistant general manager of the Lowe Bros. Co., Dayton, Ohio.

Mr. H. E. Shriver, until recently assistant chemist at the South Carolina Experiment Station, Clemson College, S. C., has been appointed to the chemical engineering staff of the Air Nitrates Corporation at Muscle Shoals, Ala.

Mr. O. L. Thomas, who has been connected for some time past with the experimental station of th E. I. Dupont de Nemours & Co., at Wilmington, Delaware, is now located at the Government powder plant at Jacksonville, Tenn., as chief supervisor of caustic soda manufacture and soda ash recovery.

Mr. William H. Hampton has been placed in charge of the development of miscellaneous gas defense apparatus under Major Waldemar Kops, Gas Defense Division, Chemical Warfare Service, Long Island City.

Mr. Frank P. Fahy, New York City, a magnetic engineer, has been awarded the John Scott Legacy Medal and premium for the development of the Fahy permeameter by the city of Philadelphia.

Mr. J. W. Coy until recently with the Canada Glue Company, Brantford, Ontario, is now connected with the American Glue Co., at Allegheny, Pa.

Dr. Harold S. Davis has been appointed to the research staff of the H. Koppers Co., of Pittsburgh, Pa., one of the largest manufacturers and operators of byproduct coke ovens, benzol and toluol plants. Dr. Davis will carry on his work at the Mellon Institute.

Miss Edith D. Borg, a sister of Myron I. Borg and Sidney C. Borg, bankers, and Dr. Alcan Hirsch, of 360 Riverside Drive, were married October 16 at the home of the bride's sister, Mrs. Alfred N. Goldsmith, 43 Fifth Avenue, the Rev. Dr. Stephen S. Wise officiating. Dr. Hirsch is one of the prominent chemical engineers of this country, and during the war he has been working largely in dyes and drugs for the United States and the French Governments.

To enable him to undertake research work connected with the use of the arc process in nitrogen fixation, Dr. H. K. Bsnson, Director of the Bureau of Industrial Research, University of Washington, has been given a captaincy in the nitrate division of the Army Ordnance Department. Until his entrance into the service Dr. Benson acted as chief consulting chemist to the American Nitrogen Products Co., of Seattle.

DU PONT AMERICAN INDUSTRIES

DU PONT DYESTUFFS

Our Development

When this company made its decision to enter the Coal Tar Dyestuff Industry there were two courses of development open.

First, to manufacture an extensive line of colors by taking advantage of the intermediates that could be purchased on the market. Second, the manufacture at the outset of a more limited number of colors, but starting at the bottom with the crudes and manufacturing in our own plants the intermediates required.

The adoption of the first policy would have enabled us to put on the market at an early date a large line of colors which would have found ready sale at considerable profit to ourselves. The second course meant necessarily that our development would be less rapid, that the variety of colors produced at first should be less great and that return upon the increased capital it would be necessary to invest could not be expected for a considerable length of time.

We chose the latter of these two courses because we believe that the only safe foundation for the development of a self-contained American color industry is the manufacture of a comprehensive line of intermediates, starting at the bottom from the crudes and on such a large scale as to make it economically sound.

Our course is of the most vital interest to the various dyestuff consuming industries, for it guarantees to them an adequate supply of dyestuffs that can never be cut off to leave them again dependent on foreign supplies.

HELP WANTED

WANTED: Chemist in large city in Great Lakes District. One familiar with the distillation of hydro-carbon oils and tars. State experience and salary desired. A. S., c/o Chemical Engineer.

WANTED Competent Chemist. One thoroughly familiar with the distillation of tar oils. State experience and salary desired. The Jennison-Wright Company, Toledo, Ohio.

Removes War Restrictions

Use of Platinum Now Permitted Without License—Fireworks Manufacture Allowed.

An important step toward a return to pre-war conditions in certain industries has been taken by Van. H. Manning, Director of the Bureau of Mines of the Department of the Interior, in modifying the restrictions recently placed on the manufacture and sale of fireworks and of chemicals used in the manufacture of explosives, and on the use of platnium, iridium, and palladium in the manufacture of jewelry and for dental and other non-military purposes. Under the order as modified, licenses will no longer be required in connection with the handling of fireworks or the precious metals named. Many of the numerous chemical elements entering into the manufacture of explosives are used constantly for other commercial purposes, and under the new order no restrictions will obtain on the handling of these chemicals when not used in the manufacture of explosives. Licenses are still required for the handling of all such ingredients when intended to be used in explosive manufacture, however.

German instrument makers at the outbreak of the war had succeeded in impressing the rest of the world with their skill to such an extent, that when the supply of German instruments was cut off, buyers imagined for a time that they would have to go without. But American manufacturers of scientific instruments rose to the occasion to such an extent that today American chemists manage to get along quite well without the output of the German factories. A trip through the showrooms of the Scientific Utilities Co., Inc., of New York City, is quite sufficient to prove that conclusively.

The Riche Adiabatic Calorimeter

The world has become familiar with the application of the vacuum principle as a non-conductor of heat in the various thermal bottles that keep liquids hot or cold for hours and days.

In the Riche Adiabatic Calorimeter this principle has been made use of for scientific purposes. Even in the crude apparatus of the thermal bottle the vacuum cup prevents the penetration of either a higher or lower temperature. In the Riche Calorimeter the vacuum cup principle is reinforced by the use of all other methods of preventing heat transmission.

To prevent any loss or gain of heat through the vacuum cup—which is merely a theoretical premise—it is surrounded by a mahogany box lined with one inch of pressed cork glued to the wood.

ACME TANKS

ANY SIZE OR SPECIFICATION

Three factories, situated in the East, Middle West and Pacific Coast, enable us to give you special service in the manufacture of tanks

We have on hand reserve supplies of air-dried woods suited for the different chemical requirements, making prompt shipments possible.

Our many years' experience in handling tanks to standard and special specifications should be of value to you. Your specifications will have our immediate and careful attention

NEW PUBLICATIONS

ANNUAL CHEMICAL DIRECTORY OF THE UNITED STATES. *B. F. Lovelace, Consulting Editor; Charles C. Thomas, Managing Editor.* Baltimore, Md.: William and Wilkins Company. 1918. Pp. 534. Price, $5.00 net postpaid.

The publishers and editors of this useful directory have kept pace with the developments in the chemical industries of the country during the year past and have made marked improvements in this, the second edition of the directory issued.

The directory now contains first of all a very complete listing according to products manufactured of the names and addresses of all American manufacturers of acids, alkalies, colors and dyes drug products, explosives, extracts, fertilizer constituents, oils, preservatives and many other chemicals essential for laboratory, technical and industrial purposes. This list is supplemented by an alphabetically arranged list of the manufacturers and dealers.

Another section of the directory is devoted to chemical engineering supplies and equipment, another to giving the names and location of analytical and consulting chemists, chemical engineers, listed first geographically and then alphabetically, a directory of the technical and scientific societies located in the United States and in foreign countries, a somewhat similar list of publications, American and foreign.

This directory should prove very useful both to the buyers of chemical equipment and supplies and those with either goods, equipment or services to sell, who wish to reach the chemical industries of the country.

HIGH EXPLOSIVES. *By Capt. E. De W. S. Colver, Dr. Met. F.C.S., A.I.A.E.* New York: D. Van Nostrand Company. 1918. Pp. 776. Price, $20.00.

The enterprise of the publishers of this volume is to be commended. As is pointed out in the preface to the book, English technical literature is sadly deficient when it comes to giving information regarding high explosives. While this deficiency became painfully obvious, as many chemists will vouch, on the outbreak of war, even today there exists very little collected information dealing with this very important topic. A chemist anxious to collate information regarding high explosives was compelled to manage as best he could by making use of his own notes gathered in the course of his experimental work and making extracts from the various chemical journals. The publication of this volume will therefore fill a gap which has long been in need of filling.

The author does not attempt to deal with all high explosives in this volume, but excludes certain compounds near the border line, including nitroglycerine, the dynamites, etc., and confines himself principally to those subjects which have in the past been neglected. He deals also with certain subsidiary used in the manufacture of high explosives in a way which, thanks to his ripe experience, will be found interesting and new.

A feature of the volume which will prove interesting to most chemists is the thorough way in which the author deals with certain explosives not yet manufactured on a commercial scale, but which are no doubt destined in the not far distant future to play more important parts in the field of explosive manufacturing.

Bringing together as it does a vast collection of information on the subject of high explosives, information hitherto for the most part unavailable to the chemist and the student, this new volume cannot help but assist the cause of further research.

Why Waste Steam?

If steam were cheap and there were no SARCOS to be had, waste could be tolerated. But steam costs more today than ever before—hence the need for the positive-acting SARCO. Smaller in size and far lower in cost, yet fully as efficient as the best float or bucket trap made—that's the SARCO. A heavy hydrocarbon oil is the acting agent on this trap's one moving part; it won't leak and it never sticks. Over a million of the type in use today. You, too, need them. Particulars of our trial offer on request.

(*Continued from page* 464)

there is a diminution in the number of the finer bands. The bands observed are much wider and more diffuse, especially in the bromine derivatives. This is supposed to be due to the damping neutralisation of the fundamental oscillations of the nucleus. When the amino-group is introduced, the complex oscillations are completely neutralised, and a single large absorption bands takes the place of the numerous bands exhibited by aniline and phenol.

Ethereal Oils.

The ultra violet absorption of a number of ethereal oils and synthetic organic substances has been examined by *Pfluger* (Physikal. Zeitsch., 1909, *10*, 406). A mercury lamp was used as radiator, a thermopile as indicator and the substances were examined in thin layers between quartz plates. The percentage absorption values for various lines are tabulated.

Purity of Terpenes.

Hantzsh (Ber., 1912, *45*, 553) shows that the purity of the terpenes is best controlled, and the compounds themselves best characterized, by means of their ultra violet absorption spectra. When the terpenes are not quite pure, fractions differing in b.p. by only 0.1° often show considerable differences in the form and position of their absorption curves. The absorption curves of the following compounds in alcoholic solution are recorded: a—pinene, d— and l—limonene, dipentene, l—a—phellandrene, B—phellandrene, sylvestrene, caryophyllene, m—and p—cymene, d— and l—camphor, d— and l—borneol, d— and l—laurinol. It is found that all these substances, with the exception of m— and p—cymene, a—phellandrene, d— and l—laurinol, and caryophyllene, show general absorption, and that solutions of the terpenes and camphors do not conform to Beer's law, the absorption of equimolecular solutions increasing slightly with the dilution. The power of absorption increases as the contiguity of the double linkings becomes more pronounced. Dipentene, d—, l—, and i—limonene show slight differences in their absorption curves, but these are probably due to the presence of difficulty removable impurities.

Bielecki and *Henri* have measured the absorption of ultra violet rays by aliphatic alcohols, acids, esters, aldehydes and ketones. (Compt. rend. 1912, 155, 456). The alcohols tested show a continuous and increasing absorption from $\lambda = 3{,}000$ to $\lambda = 2{,}144$, which augments rapidly with the number of $.CH_2.$ groups in the molecule. The monobasic acids show an absorption about 2,000 times as great as that due to methyl alcohol. Oxalic acid produces an absorption 30,000 times as great as that of methyl alcohol, but when the two $\cdot CO_2H$ groups are separated by one or more $\cdot CH_2\cdot$ groups, the absorption is about fifteen times as great as that of the monobasic acids.

available in your own Laboratory

Every Chemical Laboratory should be equipped with a source of Ultra Violet Rays.

The R. U. V. Ultra Violet Ray Lamp is especially recommended to those chemists who have failed to get desired results with the ordinary form of lamp.

POINTS OF SUPERIORITY OF R. U. V.

As an indication of its superiority, it has been proven that the R. U. V. Lamp yields twice the usual ultra violet component.

The increased radiation insures rapid developments of possible reactions.

The lamp is adaptable to various kinds of vessels. High efficiency is assured by manufacture of frame from new and clear quartz exclusively.

There is perfect electrical control.

BOTTLED GOODS
Made More Attractive

Whatever you put up in bottles, whether for the table or the medicine cabinet, or perfume, you can get the merchandizing value of a more attractive bottle by using "Elarco Velvo."

This is a new, remarkable discovery that enables the frosting or dimming of cheap glass bottles, so that they look like expensive, well-made containers, not hydrofluoric acid; no danger to hands or apparel; a few cents per gross to apply; the cheapest way of solving the problem of the high cost of containers, if you use glass. Write at once.

Our New Factory for the Manufacture of Pure Fused Silica, known as

SIDIO

has just been opened in New York City. A part of the output has already been assigned to the Government, but production is on such a scale as will enable us to meet your needs promptly.

SIDIO Ware is coming into wide use, both because of its low cost compared to platinum and other wares which it replaces, and also because of its technical superiority.

SIDIO withstands rapid temperature changes, it may be exposed to a continuous temperature of 1200° C. SIDIO has a coefficient of expansion one-seventeenth that of glass or platinum.

SIDIO is especially adapted for Combustion and Pyrometer Tubes, Sulphuric and Nitric Acid Condensing and Cooling Apparatus, high temperature gas analyses.

SIDIO is an American-made Product. Manufactured under American Patents. When you order fused silica SPECIFY SIDIO.

Bring Us Your Dyestuff Problems

The application of the dyestuff to textiles is as much an art as the production of the dyestuff.

Dyeing is a chemical, not a mechanical process. An intimate knowledge of the possibilities of every dyestuff is often necessary to meet the particular requirements of the consumer, and the variation of local conditions, due to differences in the quality of water, steam, and chemicals makes the dyehouse problem an individual one.

Because of this individual factor the technique of the application of dyes commands today, as it has done in the past, the best talent among those distributors who cater to the highest class of trade.

The technical department of this Company is manned by chemists who have been picked because of their expert knowledge, practical experience, and demonstrated ability. Well-equipped laboratories are maintained at our different offices, for the service of our customers.

You are invited to submit your problems. Your questions are welcome. Our advice in answer involves no obligation on your part.

DECEMBER, 1918

The services of The Chemical Engineer are always at the disposition of its readers: most of them from time to time are confronted by problems, which they find difficult or impossible of solution. At these times may we not offer them our assistance? Perhaps a line or two to us may result in you getting in touch with the man who possesses the information you need.

ECONOMIC geography will play no small part in the readjustments effected by the peace conference shortly to sit in Versaille. President Wilson was accompanied to Europe by a staff of experts on economic geography and it may be safely predicted that both the Allied and Teutonic representatives at the conference will attend similiarly supported. In the discussions which will as a result inevitably occur, due stress will undoubtedly be laid on the part possession or ready access to raw materials essential to the maintenance of the basic chemical industries of the various nations involved wlil play in preserving the future peace of the world.

Germany early saw the national and international importance of applied chemical knowledge and her reluctance to give up Alsace-Lorraine was no doubt due to some extent to the fact that "the lost provinces" contained undeveloped potash deposits equal in richness to that of the famous Strassfurt mines in Central Prussia. The frenzied attempts made by the Imperial Government before the revolution to retain its hold on Belgium and Northern France were no doubt actuated by a similar appreciation of the chemical and industrial possibilities of the two regions.

The Lorraine district annexed in 1871 and now in the possession of the Allies contains an iron reserve of about 1,800,000 tons and yielded according to German figures about three-quarters of the total steel output of the German Empire. The adjacent French territory until the declaration of the armistice in German hands contained an ore reserve of about 3,000,000 tons of richer ore.

The potash deposits of Alsace-Lorraine produced about one-tenth of the total potash output of the German Empire in pre-war days.

When Germany is deprived of Alsace-Lorraine she will be shorn of two of her most powerful means of disturbing the future peace of the world, the source of her iron and steel industry and her potash monopoly. The importance of her retention of nine-tenths of potash resources will be considerably minimized by the fact that practically all the Allied nations have since the outbreak of the war managed to find other sources of potash more or less adequate. What the United States has done in this direction is well known and, judging from reports emanating from the British and French capitals, both oountries look forward in the not far distant future to a potash supply originating in their own dominions.

TOO much stress cannot be laid upon the importance of the point emphasized by Mr. Burwell S. Cutler, chief of the Bureau of Foreign and Domestic Commerce, in his recent speech before the American Association of Speciality Manufacturers. The war, Mr. Cutler pointed out, had taught the American manufacturer the need for scientific accuracy; he hoped that this appreciation of the value of applied science would be applied to the conduct of their peaceful occupations.

To say that the United States has come from the conflict with fewer scars than the other allied nations is to utter a truism that it is obvious to those who are at all acquainted with the conditions in Europe. But while this fortunate condition of affairs is quite widely appreciated the economic results of this condition are not. The industrial organizations of not only the Allied nations but of the members of the Teutonic confederation as well, in the course of the life and death struggle which resulted in the eventual collapse of the latter, were subjected to a conditioning process, if the phrase may be used, which was only beginning to affect the American industrial fabric when the armistice was declared.

The fourth annual meeting of the Technical Association of the Pulp and Paper Industry will be held in connection with the annual meeting of the American Paper and Pulp Association, February 3 to 6, 1919.

To Protect Dye Industry

Dr. F. W. Taussig Says Tariff Commission Will Shortly Introduce Bill

DR. F. W. TAUSSIG, Chairman of the United States Tariff Commission, in an address delivered before a meeting of the American Dyestuff Manufacturers' Association, on December 6, gave notice that it is the intention of the Commission to introduce a bill into Congress, aiming to give the American dyestuff industry a greater degree of protection against foreign dyestuff manufacturers.

"The Tariff Commission has given prolonged and careful attention to the dyestuff problem," said Dr Taussig. "It has secured a thoroughly competent expert staff of its own. It has conferred in the most painstaking way with the officials of the Administration, with the representatives of the customs division of the Treasury, with consumers and with manufacturers. It has proposed and elaborated a bill that conforms to the conditions which I have just indicated. That bill endeavors to make effective the policy adopted in 1916, and also to show the way to some moderate extension of that policy in new directions. The legislation of 1916 was in many respects a great improvement on what preceded. But defects have already appeared, and there is beyond question occasion for amendment. Evasion of some of the salient provisions of the present law is possible, especially through the importation of intermediates which are nearly advanced to the stage of finished dyestuffs. The bill prepared by the Commission goes over the list of commodities with care, rearranges the enumeration of intermediates and finished dyes in such a manner as to prevent evasion, and removes some anomalies which clearly need attention. It raises frankly the question whether the specific duty of 5 cents which was not applied by the act of 1916 to indigo and to all indigoids, whether or not obtained from indigo, natural and synthetic alizarin, and dyes obtained from alizarin, anthracene, and carbasol, should be made applicable to these new excepted commodities. This opens a question of policy, but one which, as we may perhaps hope, will be dealt with irrespective of general party differences."

Mr. A. A. Wells, of the New Jersey Testing Laboratories, will leave shortly for the Far East on a mission connected with the investigation of the oil resources of Japan and Manchuria. Mr. Wells expects to spend a year and a half in the East in connection with this work. It is understood that this investigation is being undertaken in behalf of a Japanese syndicate, with American headquarters in New York City.

J. A. Chambers, 90 West Broadway, has been appointed New York representative of Reckitts (U. S. A.), Ltd., of Great Britain, manufacturers of starch, blueing and washing compounds.

The Bayer Company Sold

German Owned Property Bought by Sterling Products Company of Wheeling, Va.

THE entire capital stock of the Bayer Company, Inc., was sold at public auction on Dec. 12 by Alien Property Custodian A. Mitchell Palmer, in front of the office building of the company at Rensselaer, N. Y., for $5,310,000 to the Sterling Products Company, of Wheeling, W. Va. The Synthetic Patents Company, owned and controlled by the Bayer Company, and the Williams Crowell Color Co., of Providence, R. I., were included in the sale of the stock. The property is subject to a Government tax of $1,034,000.

While the sale must be approved by a special committee, of which Otto Bannard is the chairman, there is little doubt that the approval will be made, and one of the largest manufacturers of dyestuffs and chemicals will pass to American hands.

There were seven bidders, one of them Paine, Webber & Co., of Boston, offering with $5,000 of the sale price. The bidding started at $1,000,000 and went by jumps of $100,000 each to $4,000,000, when it increased at $50,000 each until $4,450,000 was reached. From that point to the finish the raises were $5,000.

The conclusion of peace will not be permitted to interfere with the conduct of the affairs of the department of the Alien Property Custodian. It is likely that after the signing of the peace treaty, legislation disposing of the proceeds of the sales will be passed by Congress.

The following sales have been announced for January and February of the coming year:

January 6—F. Ad Richter Co., New York, toys and medicines.

January 8—New Brunswick Chemical Company, New Brunswick, N. J.

January 15—Williamsburg Chemical Company, Brooklyn, N. Y.

January 15—Riedel & Co., New York, drugs and chemicals.

January 16—American Linters Company, Boston.

January 23—Tropon Works, New York, manufacturers of proprietary medicines.

January 30—Ceresit Waterproofing Company, Chicago, Ill.

February 4—Chromos Chemical Company, Jersey City, N. J.

February 5—J. P. Devine Company, Buffalo, N. Y., manufacturers of vacuum dryers.

The National Chemical Products Company announces that M. Beardsley, formerly manager of their Philadelphia office, is now in charge of their New York office, 120 Liberty street.

Lieut.-Col. Harrison, controller of the chemical warfare division of the British army, died on the sixth of November of pneumonia.

Southern Californian Industries Growing

Stimulus of War Conditions Has Served to Develop Potentialities of Western State Forty Millions Already Invested in State's Chemical Industries

By MORRIS M. RATHBUN,
Los Angeles Chamber of Commerce.

HOW many well informed industrial chemists in the United States, asked for a list of important chemical producing regions in this country, would place California on the list?

Perhaps few would be inclined to do so, but she belongs there, nevertheless.

Growth of the chemical industry in California during the last two years, due, of course, to the war, has one element in it distinctly separate from similar expansion in other sections of the country where the industry already was of formidable proportions.

In California, before the war, chemical manufacturing might be said to have been an embryo undertaking. Roughly estimating the amount of capital invested in manufacturing plants and in equipment two years ago, a conservative figure would be $8,000,000, and even allowing for smaller plants, overlooked in a general summary, hardly more than $2,000,000 could be added to the total.

Now, almost overnight, California chemical manufacturing has become a husky infant and, again conservatively, more than $40,000,000 is tied up in the industry.

California has just begun to realize what chemical manufacturing means in money value, economic importance and in national and international strategy.

In a State where 40 out of 46 crude ores are to be found in inexhaustible quantities within easy reach of unlimited, cheap power and adequate rail and water transportation, what should be a proper estimate of the possible future growth and permanence of chemical manufacturing on a huge scale?

Aluminum Deposits Also.

Beds of aluminum, found within a few miles of Los Angeles, will, it is believed, receive even greater attention after peace is signed than under war conditions. Allied industries, for the manufacture of aluminum utensils and other supplies are organized and waiting in anticipation of the great expansion expected to come with the re-establishment of normal conditions.

Desert brines, in great quantities, are producing calcium chloride—calcium chloride that tests the equivalent of any chloride produced in the East. Also, calcite and gypsum deposits of the highest quality are available for any demand.

A few others, described briefly for rapid scanning are: Lead, large quantities of ore, but virtually untouched at present; gold and silver, mined extensively throughout California; tungsten and molybdenum, important deposits in Los Angeles county; carbon, principally obtained from oil; sulphur, in large deposits near Owens Lake; copper, mined both in Northern and Southern California; manganese, adequate, apparently, to any demand; magnesium, great deposits, from which 1,000 tons are daily being shipped; epsom salts, "as good as anything produced in the East" and in large quantities. There are many others that might go on the list, such as bismuth, chromium, arsenic, zinc, antimony, boron, mercury, silica, fluorine and chlorine—and then the list is not complete.

The dye industry, always lying in wait for chemicals and for chemical by-products, is looming on the California horizon as a "war baby" that must be carefully nursed and murtured for the big industrial competition that approaches.

The Lower California Chemical Company, at San Diego, has erected units of a plant to be devoted to the manufacture of orcein dyes from the orchilla weed, a moss which grows in unlimited quantities near the coast of Lower California. For these dyes it is claimed that they are equal in every test to foreign dyes, and the cheapness of obtaining raw material and relatively low cost of manufacture are urged as additional claims of their excellence.

Manufacture of Dyes.

Using the by-products of local oil refineries and gas plants the Internal Dye Products Company, of Southern California, has equipped a plant near Los Angeles for the manufacture on a large scale of aniline dyes.

The largest output of the citric acid in the United States now comes from California. And here the famed citrus industry of the State appears in a new role. Millions of lemons, known to the trade as culls, are being utilized in citric acid production. The W. J. Busch Company, with headquarters in England, and with large interests in the lemon growing districts of Italy and Sicily, is one of the large firms now permanently located in California for the manufacture of citric and other acids.

Grouped about the Searles Lake deposits of Sodium and potassium salts, the Solvay Process Company, the American Trona Corporation, the Pacific Borax Company, and smaller enterprises, are manufacturing large quantities of the various salts available from the unlimited deposits. New units of existing plants, calling for the expenditure of millions of dollars, are in process of construction.

Emboldened, it may be, by the profitable past and the present successes, California's manufacturing chemists are seeking to assure a bright future by adding one more great crude to their credit—nitrate. It is whispered, literally that, that chemists already have located likely beds of nitrate mud. Should the reports prove true, and nitrate should be found in sufficiently large quantities, only the transportation problem will stand in the way of either an elimination of the Chilean importations or in a decided adjustment downward in the cost of the Chilean nitrate with the coming of competition from California.

Capital, always coy with strangers and new undertakings, has broken no precedents in its attitude toward the growing, but nevertheless continuously struggling, chemical interests in California. Some developments seemed almost too good to be true, others looked uncertain or visionary, but, on the whole, supply of capital and potential chemical manufacturing development in California are approaching a more even basis.

Many local California enterprises, the stock raisers, the orange growers, to a certain extent the oil interests, are looking more favorably upon the chemical industry as good soil for investment.

Growth is a slow process, but any Californian, whether he be a native or a resident of only a week's adoption, will tell you, and come rather close to convincing you, that anything started in California is bound to be finished not only with success, but with greater success than could be found in any other section of the globe.

Perhaps it would be difficult for many to agree with the optimistic prophecy of C. W. Hill, pioneer chemist and manufacturer of Los Angeles, who sees California as "the possible future location of the largest chemical producing activity of the world."

Rich in Resources.

Of the 40 odd crudes or elements found in California, 28 are being manufactured in the State itself and about 12 are being sent to the East for refining. An elementary study of freight rates and refining costs can convincingly demonstrate that California refineries are the cheapest and, therefore, the logical solution of the production problem.

Now, the very obvious question arises, "Where did California find all this marvelous array of crude ores, heretofore undiscovered, undeveloped and unguessed?"

In the larger sense, by far, the answer is: The desert!

When the war came, shutting off Germany's for-many-years-taken-for-granted indispensibility in the chemical world. American chemists were forced to act, not only to insure a good, fast black in a neat, well turned silk stocking, but to step out with something not only "just as good," but better in explosives, munitions—a thousand essential things—than Germany herself had produced.

Eastern manufacturing met the situation by increasing and extending production and improving the product. California chemists waded into the problem and created an industry. Their achievements amount to nothing less than that.

Who has not seen the famous "20 mule team" and immediately identified it with California? California and borax? Outside of borax, gold and silver, and some carbonate of soda, what other chemicals have been significantly identified with California?

Under the whip of necessity, California chemical manufacturers, or, rather, potential manufacturers, sent men out into the hot, arid, unfruitful California desert and there was discovered an Aladin's garden of crude chemicals merely awaiting, in many instances, the persuading force of a surface scoop or the revealing power of a few lusty picks and shovels.

Some few went into the sea, and from the giant kelp, or seaweed, beds of the Pacific Ocean reaped a dripping, slimy harvest that later, reduced to char, made the first pretentious challenge to the German world-monopoly of the potash supply.

Potash Industry Growing.

This kelp-potash industry on the Pacific Coast is a permanent activity. The giant kelp beds are renewed within from two to four months after the elaborate kelp-cutting devices, mounted in many cases on self-propelled barges, reap their harvest. The federal government has under consideration comprehensive transplanting of the Pacific kelp in Atlantic waters.

And the kelp interests are beginning to branch out and ramify. Iodine from kelp is a proven success, and quantities of dyes, and a certain kind of glue, which, under special test, "tore the surface off of glass," are being manufactured from the sea growth.

Of course, there is Searles Lake, with all that the name implies and signifies. One of the first big desert "finds" proved to be strontium, heretofore imported almost exclusively from England and Germany. Three extensive deposits of strontium sulphate, and of deposit of strontium carbonate, were discovered within easy distance of Los Angeles.

Immediate result: Two local plants erected, equipped and in full swing for the manufacture of nitrate from carbonate, and a string of freight cars speeding along to deliver the crudes to Eastern chemical manufacturers.

Then, Mr. Thomas A. Edison, who uses so much of it in his batteries, was not the only person in the United States who welcomed the news that lithium, in large quantities, had been found near San Diego. It is claimed that these San Diego deposits are virtually supplying the entire demand for lithium in the United States at the present time.

Discovery of large nickel deposits, said to rival the famous Sudbury deposits in Canada, has been made near Los Angeles and California manufacturers already have succeeded in interesting Eastern and Middle Western capital in the prospects.

While large bodies of iron pyrites have been found in Riverside county, lack of an adequate supply of fuel, coal, in this instance, has postponed for a time working of the ore in large quantities.

Business Men Must Be More Scientific

Chief of Bureau of Foreign and Domestic Commerce Wants War-Time Precision to Be Carried Over Into Peace-Time Methods—Should Be No More "Hunches" in Business.

A TELLING plea for scientific accuracy in commerce and industry was made by Burwell S. Cutler, chief of the Bureau of Foreign and Domestic Commerce, speaking before the convention of speciality manufacturers at Cleveland, on November 21. The war had taught American manufacturers the basic necessity of scientific precision, Mr. Cutler acknowledged, but there was, he claimed, still much room for improvement. While under the pressure of war time needs, American manufacturers and business men had placed their affairs under the supervision of the best scientific brains to be found in the country, this same attitude towards scientific methods should not be permitted to pass with the coming of peace.

"Doing business 'on a hunch' from now on will entail overhead costs that spell annihilation for the producer or merchant who must meet severe competition," said Mr. Cutler.

"No longer can we depend upon the very easy conditions which have heretofore covered up our mistakes. In the early days of this country our tremendous natural resources on the very surface of the land and an endless chain of immigation, providing labor and customers, produced in combination a market from ocean to ocean and from semitropical Mexico to the Arctic region that would absorb almost any product fairly attractive. Excessive overhead costs, due to lavish use of men, materials and time, were easily covered in prices which could not be resisted in all localities; that is, enough purchasing public might be found here or there to keep us going, regardless of lower prices from competition. Distances in the country created transportation costs in many cases so high that they over-shadowed the difference in price between an article highly priced from one producer and the same article at a more reasonable price from another quarter. We had not yet reached the European stage of intensive production and marketing amongst crowded cities within easy range of one another.

Need of Co-operation

"Things are different now. Our industrial capacity in many directions exceeds the normal demand. A sign of this is found in the widespread concentration of trade individuals into association for the purpose of eliminating self-destructive competition on the part of those units who do not respect actual costs and the necessity of trade integrity. By mutual enlightenment they hope to banish ignorance and market treachery. Another sign of over capacity is the attraction to overseas trade that is operating on every hand.

"Likewise, we have seen many a business concern dashed on the rocks of its own temerity. The appalling percentage of business failures in the United States is due very largely to ignorance: ignorance of cost accounting, ignorance of market, ignorance of proper production methods and ignorance of the human element composing labor. As a nation we have generally depended on luck and hustle to produce the big results of which we are so fond. Evolution, stability and a long look into the future have appeared to us somewhat superfluous to success on a big scale. We have been looking fondly at the size of the superstructure and have paid little attention to the foundation. I do not attribute this attitude to all American enterprises, for I must except some concerns of national scope whose foundations are laid solidly in the concrete of study, experimentation and laboratory research. And yet the early history of many of them shows instances of deplorable losses through neglect of facts that should have been ascertained before certain markets and market methods and financial outlays were undertaken.

European Competition

"Outside of our own boundaries we are more certain than ever to meet the competition of merchants who know thoroughly what they are doing. The European merchant is a grubber after facts. He studies his field like a jewel appraiser with his microscope, like a professional taster of teas with a sensitive mouth, like a lace buyer with his millimeter rule. His banks go carefully and patiently into the personal life of a possible customer; his official advisers take into account even the political views of a consignee and his utilization of racial preferences for color, style, size, etc., is infinite. His habit of action is still that of a painstaking artisan who slowly fashions a commodity and then carries it from household door to door, inquiring about the health of the family while his commodity undergoes pitiless inspection upside and downside by the entire household. He does business minutely on a large scale.

"So indeed do many of our largest concerns, after they have reached the point of size where laboratories and a scientific staff can be afforded. In organizations of that scope, incidental or overhead expenses run into such high figures that savings, small in point of percentage of total output, are large enough to justify elaborate methods of economy; it is noticeable that success in competition with European producers and merchants has been confined principally to concerns which could afford the refinements of cost control. That is one reason why I cannot condemn aggregations of capital and labor under a signal organization. Against the possibility of their superior strength being used to throttle competition and to fix extortionate prices—an offense that is seldom committed— I credit them with power of employment and livelihood to the greatest number of people. The resources and the men involved turn out many more units of production than would emanate from an equal amount of men and resources in the control of many separate individuals. Trade associations are born with the same instinct to join forces, not in a scheme of piracy but for human and economic salvage. By far the best educated producers that I know are those who have studied their problems in association. In Europe today unified policy and action have become an obligation forced upon the trades by the several Governments.

"What I mean by commercial education is not a conglomerate of knowledge about trade in one man's hand. The acquisition and retention of too much data can easily sap the creative energy necessary to forward vision and progress. I do insist, however, on the analytical habit of mind that demands the basic facts of a business proposition. I would have the manufacturer of woolen clothing know something of wool from the point of its original source to its transformation into textiles; a manufacturer of buttons ought to know the entire history of vegetable ivory, galilith and like substances; the cotton textile merchant should carefully watch crop movements, prices, sales, etc.—all to the end of buying and selling at the right time. One cannot over-emphasize the advantage of being in point of information ahead of current conditions."

Plant's Fate Not Settled

The final fate of the big explosives plant at Nitro, sixteen miles from Charleston, N. C., is yet undecided. The Thompson Starrett Company, construction agents for the War Department, have filed an application for abandonment of contract. Five of the units of the plant have been completed and work on the other two units has been stopped. Work on these two latter units is being, however, to protect machinery, etc., when a shutdown does take place.

At the third annual meeting of the National Wood Chemical Association, the following officers were elected: W. L. Saunders, Cadillac, Mich., president; John Troy, Olean, N. Y., vice-president; F. J. Goodfellow, Bradford, Pa., secretary-treasurer.

Importation of crude saltpeter during the eight months ended with August amounted to 4,900,032 pounds, against 7,529,180 pounds in the same time last year and 9,258,084 pounds in the corresponding period two years ago.

Lignite Experts Tour U. S.

Canadian Scientists Engaged in Survey of Lignite Resources.

TWO Canadian scientists, representing the recently formed Lignite Utilization Board of Canada are now touring the United States on a mission primarily concerned with an inspection of the lignite resources of the United States. After spending a week in New York City, they went to Washington and thence to the various leading centres in the Pennsylvania coal district. It is their intention to travel through to the Pacific coast. Early in the New Year they will return to Montreal, the eastern headquarters of the Lignite Board, after making inspections of the various coal and lignite districts of the Canadian West.

The Lignite Board of Canada is a subsidiary of the Advisory Council of Research of Canada, organized early in the war by the Canadian Government. For two years past the Council has been doing a great deal of work in the direction of making more intensive and economical use of the Dominion's resources and it is in line with the further development of this policy that the two scientists are touring the United States.

The coal problem of Canada since the United States entered the war has been very acute. The obvious need for a domestic source of supply has drawn the Government's attention most forcibly to the need of making use of the large supplies of low grade coal available in the Canadian West.

At present Western manufacturers both American and Canadian prefer to use the American bituminous coal, in spite of the high prices rather than make use of the Alberta and Sasketchewan lignite.

Canadian scientists believe that the low grade coals of the West can be made commercially valuable and to study ways and means of bringing this about the Lignite Utilization Board was formed.

The coal deposits of Saskatchewan furnish coal of the lignite variety only. As some of the physical qualities of this coal prevent its economical and efficient commercial use, the yearly production has so far been small. This despite the fact that a rapid increase in population has increased the fuel demands of this part of the West very considerably.

The production of Lignite in 1915 from thirty-three Saskatchewan collieries was 240,107 tons; in 1914 the production was 232,299 tons. From figures at present available the production this year will be slightly larger than it was last year.

The production in Alberta in 1915 was 1,682,922 tons. During the first eight months of the current year it was 1,781,235 tons.

Some Processes of Rubber Manufacturing

he Preparation and Mixing of Various Compounds—The Reclamation of Rubber—Manufacture of Rubber Substitutes—The Process of Manufacturing Automobile Tires.

By FREDERICK J. MAYWALD, F. C. S.

THE rubber manufacturer uses many other materials besides crude rubber. He uses first of all mineral fillers of various kinds such as niting, white lead, litharge, or sublimed white lead, ide of zinc, asbestine, various coloring substances, ch as iron oxide, ultramarine blue, lampblack, etc., fteners such as vaseline, palm oil, tars, etc., and bstitutes, so called, which are not at all substi-tes, but are simply fillers or cheapeners and are ade by treating oil, either vegetable or mineral, ith sulphur chloride, which produces white sub-itutes; or boiling the oil with sulphur, which pro-ices the brown or black substitute.

Then there are large quantities of reclaimed rub-rs or shoddies used. These shoddies are prepared om about every variety of rubber known. If one preparing a shoddy from tires, the bead is re-oved first of all, the rest of the tire is then ground a crushed mass with proper corrugated rolls and is crushed mass is then placed in large boilers (in ie alkali process) and boiled up for a long time ith a solution of caustic soda, under pressure and relatively high temperatures. This treatment de-roys the cotton fibre and removes some of the free unvulcanized sulphur, some of the fillers such as nc oxide, some of the lead, etc. After the boiling ocess is complete, the rubber is blown out of ie cooker, the liquor contained in it is drained vay, the rubber washed, dried and finally "sheeted it." After sheeting out the rubber is run through hat is known as a refiner. This consists of two illers which can be set very close together so that e rubber comes out from between them, with a iickness of about one five-thousandth of an inch. his thin sheet is then passed under a heavy iron ir, known as a "doctor," which is a sort of a raper. This scraper removes any unaltered rub-r from the sheet. These thin sheets of rubber are ien rolled up and the rubber, being still warm and astic, soon packs into a solid mass.

The Acid Reclamation Process

In the acid process of reclaiming, the rubber is eated with a dilute solution of sulphuric acid, ashed and finally goes through the same process s the alkali reclaimed rubber. These are the two rincipal processes. There are some small amounts f rubber prepared by the old mechanical process, which the rubber stock is ground to a fine powder, he cotton being blown out by compressed air. Very ttle of this type of reclaimed rubber is made to-ay, the larger portion of the reclaimed rubber be-ng prepared by the alkali process. There are, in eality, forty grades of reclaimed rubber or rather of raw stocks from which reclaimed rubbers are made, sold in the market.

Where a rubber compound has to be soft enough to be driven through a fabric, as in the preparation of tire fabric, there is added to the Hevea or other high grade rubber a softer rubber such as Pontianak, Accra Flake, etc. A rubber compound is built up along definite lines, having always in mind the purpose for which the finished product is to be used. If we had to build an inner tube, we would take a high grade rubber, such as smoked sheet, add to it a certain amount of zinc oxide, some whiting and sulphur; if a red tube were wanted we would use antimony sulphide, either golden or crimson, or a mixture of the two, depending upon the color desired. If we were building a gray tire we would use the same rubber but would use a filler of litharge, whiting and possibly some zinc oxide. For a tire tread, we would use a plantation rubber such as a smoked sheet, add a certain amount of a softer rubber, such as Caucho ball and use for the filler principally zinc oxide together with smaller amounts of whiting, aluminum flake or similar filling material and sulphur. If on the other hand we were going to produce a cheap stock, such as moulded hose or packing, we would probably use very little if any new rubber, depending chiefly upon reclaimed rubber, adding to it whiting, a softener such as vaseline, sulphur, perhaps oxide of zinc, litharge, magnesia and other fillers, the nature and amount of these fillers depending upon the article to be manufactured. If the manufacturer wishes to produce a hose to withstand acid, we could of course use none of the fillers soluble in acid, such as zinc, whiting and whiting but would use in place of it flaked silica, or tripoli. If we wanted a softer rubber for frictioning, as for building the carcass of a tire, we would use a plantation rubber of one of the softer grades, add to it a certain amount of Pontanak or possibly Accra Flake and a small amount of filler, usually zinc, or possibly whiting and sulphur. These would give us certain definite products, with certain specific working qualities, ageing qualities and what might be called "life tests." For instance, a man might build a tire tread from nothing but Para rubber and zinc oxide and obtain a tire which was very tough and hard but which would not have the wearing qualities of the same tire if built from softer rubber or partly with a softer rubber. He would not get the wearing quality from a tread stock containing nothing but rubber and sulphur that he would get from a tire compound in the way in which I have described.

The Manufacturing Process.

In making rubber goods, whatever the compound nay be, it is weighed out in the compounding room nd the batch, as it is called, is sent to the mill. The nill consists of two heavy rolls, revolving toward ach other at different speeds. For instance, in a ertain sized mill, these rolls might revolve at 12 nd 16 revolutions a minute. In a model plant vhich I have set up in my laboratory there are two uch machines, one with two rolls, the other with hree. In the two roll mill, the rolls are set horiontally against each other, while in the three roll nill, the rolls are set one above the other. The hree roll mill is what is known in the rubber trade s a calendar. The rolls in both the mill and the alendar are hollow and each roll is fed by two ets of pipes, one set for cold water, the other for team. Your mill man uses either as necessity rises. The grinding of rubber in one of these mills reates considerable heat, due to the friction, and as n excess of heat will destroy the rubber and after he sulphur has been added may even cause the ubber to vulcanize on the rolls, it is necessary vhen the rubber reaches a certain temperature to urn on the cold water. The mill man may at the tart warm his rolls by allowing a small amount of team to go into them but in many mills it is the ustom to dispense entirely with steam lines on the olls.

The Making of the Stock.

In making up his compound the mill man first hrows onto the rolls of the mill the rubber. This s ground down until it is soft and plastic. The dry llers are then worked. The plastic rubber takes ese fillers up readily and the excess which falls etween the rolls is caught in a pan below. From his pan the material is collected and returned to the olls.

During the milling operation the rubber is frenently cut from the rolls, to allow it to cool on he under side This also improves the "mix." Vhen all the compounding ingredients are mixed in, he stock is cut from the roll and rolled up. It is hen once more run through the mill in sheet form. his operation is repeated until a thoroughly uniorm product is obtained. From the mill the stock sually goes to the cooling room, where it is allowed cool off and to recover its "nerve."

If the manufacturer wishes to turn out tires or re treads, the rubber is once more warmed up and nade somewhat plastic on the mill and then run rough the calender to be made into sheets. For e sheeting process these rolls run at the same eed and a series of knives is fitted to the front of e calender. These knives cut through the stock d are set at fixed distances apart, so that the ck removed from the calendar will be cut into e right lengths for its immediate use The stock fed on to the calender from time to time and the calendered stock is run out between sheets of unbleached cotton. It is possible of courst to set the calender rolls to any gauge or thickness that is wanted. Tube stocks are usually calendered at 1-64 or 1-32 of an inch.

The Making of Tire Treads.

A tire tread is built up in step formation, with five or six or even seven layers, each layer being narrower than the one beneath it. If frictioning is to be done, that is if tire ducks are to be used, the calender is set with two sets of gears and the keys are removed from the set of gears that run at even speed to the opposite end which produces variable speed of the different rolls. This gives a driving or grinding action and forces the rubber into the fabric. The stock in every case is worked between the middle and the lower roll. In the case of frictioning, the cotton fabric is run between the lower and the middle roll and the rubber stock adherent to the middle roll is driven into the pores of the fabric. Later on a skim coat, as it is called, may be put on top. This frictioned stock is then taken away and cut to the required width and length. In tire fabrics, hose, etc., the stock is usually cut on the bias.

If a moulded hose or tubes of various sorts are to be produced, the stock is taken from the mill and put through a tubing machine. This machine is built to force the rubber out of a given sized die. If a tube is required, the die has a centre core, around which the rubber must flow. Thus in a moulded hose the central tube is first produced from a tubing machine. It is then semi-cured, as it is called, in other words, partly cured or vulcanized. This cured tube is once more run through the tubing machine and a thin coat of unvulcanized rubber put over it. The coated tube then goes to the braider, where the layer of cotton is braided on to it. After this the tube is again run through the tubing machine and another coating of unvulcanized rubber applied. Another layer of braiding is laid on and finally the outer layer of rubber applied. The hose is then cut into long lengths, placed in molds and cured.

Rubberizing of Fabrics.

In the production of rubberized fabrics, such as raincoats, the rubber compound is placed in a churn or mixer, a certain amount of gasoline added and the whole run into a thick dough of uniform composition. This dough is then applied to the cotton fabric on what are known as spreaders. The cloth passes under a knife called a "doctor" which is so set as to permit a certain amount of the rubber dough to be deposited on the cloth. The cloth is then conducted over a steam table where the solvent is driven out.

Many other types of goods are produced in special ways. Surgical goods, such as transparent

Notes on the Occlusion of Gases in Metals

English Scientist Before Faraday Society Discusses Some Phases of Reactions Between Gases and Metals.

By ALFRED W. PORTER, D.Sc., F.R.S. *

IN 1817 Humphrey Davy noticed that combination could be induced between various gaseous mixtures when brought into contact with platinum foil or wire heated to a temperature "short of redness." Döbereiner (1822) showed that spongy platinum induces combination between hydrogen and oxygen t ordinary temperatures. Other solid substances possess the same power, though to a less degree. Fluorspar, marble, and mercury did not exert any perceptible action even when heated up to the boiling-oint of mercury. Faraday explained the action as due to a condensed layer of the gases on the sur-ace of the solid. Platinum, palladium, and carbon all possess the power of absorbing (or adsorbing) arge quantities of gas. The name "occlusion" was given by Thomas Graham to the property of ab-orbing hydrogen at a red heat and of retaining that gas at a temperature under redness for an indefinite ime. The occlusion of hydrogen was most marked in the case of palladium even at low temperatures. The palladium was exposed to hydrogen between 90° and 97°C. for three hours and then allowed to ool in the gas for one hour and a half. When heated by a gas flame and pumped off, the metal yielded 43.3 times its own volume of hydrogen.

The name "occlusion" probably covers a number of different phenomena which take place either singly or in conjunction. These can be enumerated under heads. Firstly, chemical combination of gas with metal; e.g., hydrogen with sodium, potassium, or palladium to form Na_2H, K_2H, Pd_2H (Troost et Hautefeuille) or PdH (Graham). Secondly, simple solid solution, either separately or in conjunction with the above; e.g., when hydrogen is occluded by lithium (T. and H.). Thirdly, solid solution; e.g., hydrogen in palladium (Roozeboom and Hoitsema). Fourthly, solution accompanied by surface adsorption. Fifthly, surface condensation under molecular forces (unaccompanied by solution); especially in pores formed by the condensing material. Sixthly, inclusion, as when bubbles, large or minute, become entangled in the molten viscous mass and cannot escape from it.

It is usually a delicate matter to distinguish between these various types in practice; and in any case the discrimination requires a very detailed examination of the phenomena.

The matter can be well illustrated by the case of the occlusion of palladium in hydrogen, which has been extensively investigated.

Graham concluded from the change of density of palladium when it occludes hydrogen that a chemical compound PdH is formed. Troost and Hautefeuille conclude from the constancy of the disassociation pressure as soon as the volume of hydrogen is no longer more than 600 volumes that the compound formed is Pd_2H.

On the other hand Hoitsema disputes the validity of this conclusion resting his objections on experiments by Roozeboom and himself.

Hoitsema applies the distribution law of van't Hoff and Nernst to these immiscible phases and concludes than when under small external pressure hydrogen occludes as monatomic molecules; but that if the volume of 2 mgr. of condensed gas is less than 0.8 c.c. (at temperatures between 150°C. and 200°C.) the condensed molecules are diatomic.

At higher temperatures the results are more complicated and have not been interpreted in detail. In all cases there is some uncertainty about the estimation of the concentration of the hydrogen in the metal, since it is not known whether (or not) it is uniformly distributed within it.

If the slope of the curves in the region of mixed phases is not insisted upon, comparison might be made with the behaviour of a liquefying gas, as in Andrew's diagram, with an apparent indication of a critical point at some temperature higher than 200°C. The two phases might then be liquid hydrogen and gaseous hydrogen; the volume of 2 mgr. being respectively about 1 and 4 c.c. at 140°C. The phenomenon would then lie in the fourth or fifth of the above groups; more probably the latter.

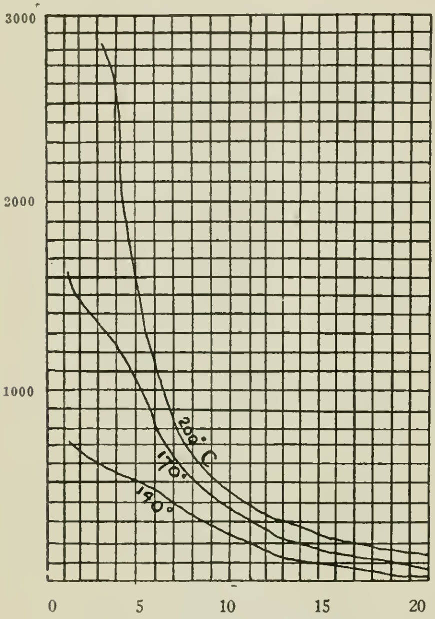
It has been objected to the condensation theory that the heat set free is far in excess of the latent heat of vaporization of the gas.

Holt, Edgar, and Firth conclude from their own investigations that hydrogen is occluded in palladium in two ways: (i) in an absorbed layer of high vapour pressure which can easily be removed by evacuation; (ii) as an absorbed gas which is non-uniformly distributed within the body of the metal. As the temperature rises the pressure of the absorbed gas increases, whilst the adsorbed layer diminishes, so that the approximately horizontal part of the curve (such as Hoitsema's) will become shorter, until at about 300°C., where the difference between the pressures of the adsorbed and absorbed portions is negligible, the curve will approximate to a straight line.

---

* *Read before the Faraday Society, November 12, 1918.*

Sieverts ‡ has extended measurements up to the melting-point of palladium (1,550°C.), and finds that on liquefaction the occlusion rapidly falls off to about half value.



Volume (in c.c.) of 2 mgr. Hydrogen when occluded in Palladium. (C. Hoitsema.)

Wolf § measures the electrical conductivity of palladium and decides as follows:—

(a) The conductivity diminishes proportionally to the occluded quantity of hydrogen as long as the hydrogen is being merely dissolved.

(b) It diminishes asymptotically as long as a chemical combination Pd_2H is being formed; i.e, from an occlusion of 40-600 volumes gas to unit volume of palladium.

(c) After this range further hydrogen dissolves in Pd_2H and the conductivity again diminishes proportionally to the additional quantity occluded.

Holt ‖ concludes that the time-rate of solution of hydrogen by palladium is not a simple function of the concentration of the gas. The rate curves consist of two portions (except in the case of palladium black), which are interpreted as referring to solution in two different forms of the metal. The smooth curve obtained for palladium black is taken to mean almost complete absence of one of these forms.

For example, the heat set free in the occlusion of 1 gram hydrogen in palladium is about 4.672 cal (Mond, Ramsay, and Shields). For the occlusion in platinum the value is 6.610 cal (M., R., Sh.). On the view that the hydrogen is liquefied in the pores it has been thought that these values ought to be identical. The heat of vaporization of hydrogen at −252.8°C. is 123 calories per gram (Dewar, 1905). It must be remembered, however, that the heat of vaporization from the surface of a solid may be expected to be much greater than from the liquid hydrogen itself. By Dupré's formula the value of the latent heat per unit-volume of liquid is equal to the value of the intrinsic pressume due to molecular attractions. These attractions between platinum and liquid are certainly much greater than between two layers of liquid hydrogen. This must be so, if for no other reason, because condensation of the gas would not otherwise occur at a temperature many times its usual critical temperature. For the same reason the heats of occlusion in pores of platinum and of palladium will not be identical. For if the pores are large enough no condensation will occur; while if their diameters are within the molecular range of the metals the specific character of these metals must have an influence.

The difference between the fourth and fifth groups is that the term adsorption should probably be restricted to the case in which true solution takes place, but in which there is a modification (either increase or decrease) of the concentration in the surface firm arising from the influence of the dissolved body upon the surface tension. This is quite distinguishable from the case of surface condensation without solution; although both are due to molecular attractions.

Sieverts * finds that iron begins to occlude hydrogen at a temperature of about 400°C., from which point it increases according to an almost linear law up to 850°; at 850°C. there is a break in the temperature concentration curve, the concentration showing a rapid increase up to 900°, after which the concentration again becomes linear up to the melting-point, when the concentration rapidly diminishes.

Amongst phenomena due to absorption of gases in iron may be mentioned the passivity of iron † and the embrittling of iron by caustic soda.‡ With regard to metals in general, the Volta effect has been often attributed to condensed gases; and in J. Brown's experiments it vanished entirely when these films were removed by boiling in linseed oil. Much modern work on this subject is being done by O. W. Richardson, H. A. Wilson, Soddy, Just and Haber, Fredenhagen, Pring, Langmuir, and many others. H. A. Wilson found that the electron emission from platinum at high temperatures was decreased to 1/250,000 of its former value by a preliminary heating of the platinum in oxygen or by boiling in nitric acid. The admission of a little hydrogen brought the current back to its former value. Soddy § found that the currents obtainable from a Wehnelt cathode stopped suddenly if the residual gases on the vacuum tube were absorbed

British Control of Acid Industry—The Manufacture of Artificial Silk—Chemicals from Seaweeds—Paper Yarn Industry in Europe—The War's Effect on Supply of Photographic Chemicals.

Acid and Fertilizer Industry.

British Control of Acid and Fertilizer Industry —Board of Trade Journal—London, England.

One of the most complete controls exercised by any department of the British Government during the war, was that exercised over the acid industry and fertilizer connected with it. The control was continuous and unbroken from the mining and shipment of the raw material down to the delivery to the consumers of the finished products.

The key industry, the manufacture of sulphuric acid, was first controlled through the control and distribution of iron pyrites, imported chiefly from Spain and Norway, the principal raw material upon which the sulphuric acid industry depends. The pyrites were controlled at all stages, prices were fixed and rationing inaugurated.

Numerous economies resulted from the completeness of control exercised by the Government. Use was found for a number of industrial by-products hitherto wasted. Niter cake was introduced into 25 trades where sulphuric acid had hitherto performed a somewhat crude function, as in the textile and dyeing trades, grease recovery and metal picking.

Another important economy was effected by the utilization of pyrites residues under centralized control. Steps were taken to work up the noncupreous residues from iron pyrites, after the sulphur had been removed at the acid works, in order to make them suitable for the manufacture of iron in the blast furnaces.

Artificial Silk, The Manufacture of

Our Increased Manufacture of Artificial Silk—The National City Bank, New York City.

The United States after being an importer of artificial silk is today one of the world's largest producers and exporters. The exportation of artificial silk stockings from the United States has reached over six million pairs.

In describing the process of manufacturing artificial silk, says this article, wood pulp is treated in most cases with caustic soda to form a sodium cellulose and is then dissolved in carbon disulphide. The product alkali-cellulose-xanthate is popularly known as viscose. After being filtered and allowed to ripen by standing, it is forced through minute holes into a liquid which solidifies the threads.

Silk goods made from this artifical fibre are chiefly remarkable for their brilliancy but have a somewhat harsher "feel." Some of the early shortcomings of the early product are being gradually overcome .

Chemicals from Seaweed

Solvents from Kelp—an Infant Industry—C. A. Higgins—American Industries—Oct. 18, 1918.

The Hercules Powder Company in an effort to alleviate the world side shortage of potash established an experimental plant near Los Angeles, Cal., to extract potash from the kelp which grows so luxuriantly along this part of the Pacific coast. The company expected that a number of other chemical by products of the process would be found commercially valuable.

The venture has already developed for the first time on a commercial scale a whole line of chemical products.

The Hercules process of producing solvents and their intermediates from kelp is, according to this writer, very simple. After being harvested and brought to shore the kelp is macerated, pumped into tanks, diluted and allowed to ferment at about ninety degrees F. after finely ground limestone has been added to neutralize the acid produced during the process of fermentation. After the lapse of fifteen days the leafy structure of the kelp is entirely destroyed and a liquor obtained which contains acetate of lime, muriate of potash, and iodides in solution. The crude salts obtained therefrom are heated in retorts to obtain acetone and the muriate of potash obtained by leaching and crystallization.

The Hercules process is productive of not only acetate salts but of propionates, butyrates, valerianates and even of the higher acids of this series. It is this series of salts which by conversion into their ethyl esters is providing the trade with an entirely new series of amyl acetate substitutes in the ethyl propionate, ethyl butyrate series.

Ethyl acetate is a well known product. It is used as a solvent of nitrocellulose in the manufacture of artificial leather, in finishing celluloid and in a great many other well known ways. Ethyl propionate and ethyl butyrate are excellent solvents of nitrocellulose, resins and gums. Ethyl propionate boils at 100 degrees C. and appears to resemble in its properties a mixture of ethyl acetate with about ten to twenty percent. amyl acetate. Ethyl butyrate boils at 120 degrees C. and resembles amyl acetate very closely in its physical qualities. These two esters it is believed will find a wide field of usefulness in the soluble cotton, artificial leather, paint and varnish trades.

Special mention is made in this article of the valerates, caproates, etc. Valerain and its salts and esters is well known in the drug and pharmaceutical trade and it seems likely that new sources will be welcomed by the trade. The esters of these acids will be sought after by the essense and perfume trades.

Paper Yarn Industry, The German

The Paper Yarn Industry in Germany—Frankfurter Zeitung, Sept. 20, 1918—Commerce Reports.

This industry has expanded to such an extent since the outbreak of the war that according to the writer of this article about 88,000,000 tons of yarn are today being produced.

The manufacturing processes are constantly being improved and as matters now stand, paper yarn can be used in the manufacture of various fabrics and garments, excepting only body linen and the better sorts of outer clothing. Workingmen's clothes, bed and table linen, curtains, sail cloth, imitation leather are all being successfully made.

German Textile Substitutes—Research Department, Bureau of Foreign and Domestic Commerce.

According to the report the third German Fiber Exposition was held in Leipzig late in August. While according to reports published in German newspapers, regarding these expositions, a great variety of products were shown, there is evident in Germany in spite of the efforts of the manufacturers to counteract it, considerable skepticism regarding the possibility of paper textiles serving as entirely satisfactory substitutes for cotton and wool.

The principal exhibit at the Leipzig show, was that of the Textilose Werke und Kunstweberei Claviez Akt.-Ges. of Adorpf, Saxony.

Besides clothes of textilose and cellulon, the products of various fibre plants such as the cat tail, some truf plants, the cotton grass and the broom were shown.

Photographic Supplies, War's Effect on.

Eastman Kodak Confident of the Future.—B. L. B. Jones—Printers Ink, Nov. 21, p. 41.

American manufacturers of photographic materials have risen to the situation in their industry caused by the outbreak of the war in Europe. Before the war, not only a large proportion of the lenses used in American cameras came from Europe, but nearly all the developers and the raw photographic paper. Today the only problem before the American lens makers is the question of quantity production. American anastigmat lens are the equal of any in the world. So far as photographic paper is concerned, a new mill almost completed, will shortly place the Eastman Company in a position of independence so far as foreign sources of supply are concerned.

According to the writer of this article the war has also taught photographers economy. In prewar days tons of discarded negatives could be found in the cellar of any long established photographer. Today instead of laying these negatives aside, emulsion is washed from the plates, silver recover from the emulsion, the glass recoated and sent again as dry plates.

Must Protect Dye Industry

Dr. J. M. Matthews Claims Government Aid Necessary

Speaking before the Philadelphia section of th American Chemical Society, on November 21. Dr J. M. Matthews, consulting chemist of this city, de clared that it had been impossible for the Americ dyestuff industry to build along permanent line under war pressure. He contended that with th restoration of normal conditions, a great amount plant equipment would have to be scrapped.

"In the approaching period of reconstructio said Dr. Matthews, "the dyestuff industry mu have room to turn around in, so that it can wit stand the normal agencies of competition In present shape, built up as it is in a more or l temporary way, if it is suddenly confronted with destructive force of unrestrained and unlimited Ge man competition, the dyestuff industry of this cou try will be faced with the danger of going down in a pile of ruins. This would be a disaster that th country cannot afford."

This situation could be avoided, Dr. Matthe claimed, by a proper policy of Government prot tion. A tariff protection of the usual kind was sufficient. Some such plan as that adopted by British Government should be tried out. Und this plan a license committee having control of imports and exports of dyestuffs should be form Such a committee should be made up of represen tives of the industries involved and the consum of dyes.

Demobilizing Chemists

Under the guidance of Major Allen Rogers, Industrial Relations Division of the Chemical W fare Service has undertaken the task of findi peaceful occupations for the thousands of chemis drafted in the chemical branch of the service si its formation.

In order to facilitate the transfer of these m from wartime work to industrial occupations, che ists are being requested to consult Major Roge in regard to their future intentions and manufa turers are being asked to let Major Rogers kn exactly what their future requirements will be the direction of chemical assistance. Major Roge address is "Chemical Warfare Service, Seventh a B. Streets, N. W., Washington, D. C."

Prof. Pierre de Peyster Ricketts, head of Ricke Inc., mineralogical and mining engineers, with offices 80 Maiden Lane, New York City, died recently at home, 115 East Seventy-ninth street, New York Ci

Make Paper From Leaves

Mme. Karen Dramson Suggests New Pulp Source

THE war has produced in France a very sharp rise in the price of paper. Before war broke out France imported over fifty per cent. of the pulp used by her manufacturers of paper from Germany and Austria. The cutting off of this source of supply, combined with the severe deforestation due to the war demand for lumber, made wood pulp so scarce and prices so high that many publications were compelled to suspend publication.

While the imminent coming of peace will no doubt eliminate some of the conditions which have made the present high price of paper in France possible, it seems likely that a scarcity of native grown wood pulp will persist in France for a great many years to come. It is likely, therefore, that a method of producing paper from fallen leaves evolved by French scientists under the stress of war time conditions will be made use of long after the war is over.

Some time ago M. Edmond Perrier, of the French Academy of Sciences, presented before that body an account of the successful experiments made along this line by Mme. Karen Dramson.

The process is very simple, rapid and inexpensive, according to M. Perrier. The leaves are first crushed by a proces which reduces the blades to a powder. This powder is carefully separated from the ribs and veins. From these the raw material for paper pulp is formed.

The ribs and veins are subjected, in the next proces of manufacture to a rapid lixiviation; then washed and bleached. The pulp is then ready for use.

The discoverer of this new material claims that it is for a number of uses in addition to its use as a paper material. First, it has a high food value, since it contains the digestible parts of the leaves with the cellulose removed. Its value as a cattle food is almost equal to that of hay, especially when mixed with molasses and compressed into cakes. Then it can be used as fuel. Compressed into cakes it may be used either with or without charcoal.

Mme. Bramson, in conection with the use of this powder as a fuel, recommends it further for treatment by means of dry distillation. Using this method she obtained a very pure charcoal, rich in calories, and easy to agglomerate. In using this process she also produced an excellent tar, having all the qualities of Norwegian tar. Other by-products were acetone and pyroligeneous acid.

One thousand grams of the leaves yielded, according to Mme. Bramson's figures 250 grams of pure carbon, 30 kilograms of tar, one kilogram of pyroligeneous acid and 600 grams of acetone.

The importance of this discovery on the part of Mme. Bramson can be seen when it is understood that France annually produces, according to estin ates made by the Director of the School of Grigo between thirty-five and forty million tons of dea leaves annually. It is further calculated that onl four million tons of these leaves would be neede to provide the paper pulp needed by France eac year. This would mean a very substantial saving t France as in 1913 she spent $20,000,000 for woc pulp all originating in either France or Austria.

It is believed that the collection of these leav could be carried on by women, children and cri pled soldiers. It is planned to either erect the mil needed for the preparation of the leaves, either i the vicinity of the forested areas of France or t ship the leaves in compressed form to centr depots.

Plan to Erect Laboratory

Plans involving the erection of a $500,000 centr laboratory building, to house some fifty labor tories, are under consideration by the Canadia Council for Scientific and Industrial Research. Th building it is planned to make the heart of a gre central industrial research institute, similar in fun tion to the Bureau of Standards at Washington a the Mellon Institute at Pittsburgh.

The scheme, which is considered essential to t future industrial development of the Dominion a the ability of the country to compete on an equ basis with the other industrial nations of the worl will, it is hoped, provide modern scientific equi ment for the investigation of Canada's raw m terials. It will serve as a national laboratory f the fixing of standards of all kinds, for the testi of materials and for the devising of methods utilizing by-products of industry at present waste

The War Industries Board has turned over the pr lem of increasing the country's potash supply to the I partment of the Interior. In announcing this chan Chairman Bernard Baruch said that this step was tak in order that a permanent department of the Administ tion might have charge of the task of emancipating American farmer from the grip of the German pot industry.

The Marcus Hook plant of the National Aniline a Chemical Company, Inc., has commenced construct on the village at Naaman's on the Delaware and work rapidly progressing on the first one hundred houses.

The Texas Gulf Sulphur Company is completing a 000 horse-power steam plant at Matagorda, Texas, in c nection with its plans for extensive development of sulphur mines. About 1,000 acres are to be developed w a daily output of 1,000 tons. It is planned to spend o $4,000,000 in development work at this point.

Losses amounting to $2,500 resulted on Nov. 13 fro fire which broke out in the laboratory of the Holl Aniline Dye Works, Holland, Michigan.

gloves, transparent nipples and other goods of that type are built up by making a thinner solution of the rubber compound and gasoline. This is applied to the surface of porcelain or wooden forms by dipping. In druggists' sundries such as water bottles, etc., the rubber is run into thin sheets, cut into shape and then worked together.

Vulcanizing Methods Used.

There are several methods of vulcanizing used in rubber factories. Rubber tires, tubes and products of that kind are placed in moulds. In the case of tires these moulds are placed in vulcanizers and steam is allowed to circulate around them. This process produces what is known as a moulded tire. In the wrapped tread tire, the tire after building is wrapped with wet cloths under high tension and the same process is applied as with the production of inner tubes, the tube being built up on a steel mandrel and then wrapped with cotton rags. Finally it is run into the vulcanizer and cured in steam of a given pressure.

In the production of mechanicals, such as valves, packages, etc., these are cured in a press. This press consists of two or more hollow plates through which steam circulates. The article to be cured is placed in a mould. This mould is placed between the two plates and steam allowed to circulate through the platens or hollow plates for a specified time at a fixed pressure.

Raincoats and goods of that kind are cured by being hung in rooms filled with steam pipes. The fabrics to be cured are subjected to the vapor of sulphur chloride for a fixed period. Rubber shoes and boots are cured by what is known as the heater process. Heaters are simply large rooms, which are heated to a given temperature by steam pipes, usually in the floors or around the walls near the bottom. A tire will be cured in one and a half to two and a half hours. It takes six to eight hours to cure a rubber shoe or boot by the heater process. Sometimes raincoats are cured in the same way by dry heat.

Finally we have the acid cure, applied principally to dipped goods and surgicals, where the sulphur chloride is dissolved in a solvent such as benzol or bisulphide of carbon. The goods are immersed in this solution for a few seconds, then hung up and allowed to dry, finally being stripped from the mould.

The Whitesboro plant of the Metallic Chemical Company has been closed and part of the workmen employed have been transferred to the company's Utica branch.

A branch of the Fabrico Co., of Dallas Texas is to be located in Quincy, Ill. The company manufactures a waterproof preparation for dressing leather belts, waterproofing tents, automobile tops and other fabrics.

Operations at the plant of the Stanley Anilin Chemical Company, Lockhaven, Pa., have been indefinitely suspended.

German Ownership Must Go

A. Mitchell Palmer Declares Against Return to Conditions

THAT the only hope for the future developm of the chemical industries of the Un States lay in the stamping out, root branch, of German owned companies in the Uni States, was the claim made by A. Mitchell Palm Alien Property Custodian, before the Bar Assoc tion of the City of New York, on the evening December 10.

"There is absolutely no hope," said Mr. Palm "for the development of American chemical ind tries under the old conditions. Chemistry m than any other science is the very foundation o far flung line of industry. You have but to lo about you, for example, at the tremendous p which colors play in all the necessities, comfo and luxuries of life to realize the grip which control of the dyestuff industry has upon the p ple. In peace and even more in war, chemis paints the whole picture of progress. Americ social and economic, possibly even her political dependence is not safe unless the industries pendent upon the development of the science chemistry are open to American genius and ener

"I cannot too forcibly repeat that the German dustrial penetration of America has not been mere friendly desire to trade and do business w the world. It has been a knife at the throat America. In the days before the war, and dur the war, most of the German-owned industrial tablishments were spy centers filled with the age of Germany long plotting against the safety of United States. They were depositories of sec information gleaned by the ubiquitous spies in German employ and without them these sp would have been almost harmless."

Mainly About Chemists

Mr. H. R. Van Wagener, of Denver, Colo., has b appointed general manager of the Canada Copper C pany and will make his headquarters at Copper Mount near Princeton, B. C.

Mr. M. H. Barnes, formerly chemist for the Illin Steel Company, Gary, Indiana, is now division inspec for the Aluminum Company of America, Maryville, T

Mr. Charles D. Test, until recently with the West Potash Works, of Antioch, Neb., has become attached the staff of the United States Tariff Commission.

Mr. Nathan Owitz, for four years general manager the J. P. Devine Company, of Buffalo, N. Y., has b appointed president and general manager of the Pe Chemical Corporation.

Mr. F. E. Smith has been appointed chief engineer w the Barber Greene Co., Aurora, Ill.

Mr. Benton Dales, formerly the head of the chemist department of the University of Nebraska, is now tached to the research department of the B. F. Goo rich Company, Akron, Ohio.

ULTRA VIOLET LIGHT

Its Application in Chemical Arts

By CARLETON ELLIS and A. A. WELLS[*]

Part XX

Massol and *Faucon* (Compt. rend., 1913, 157,386) have made a study of the ultra violet absorption spectra of some normal primary, secondary, and tertiary alcohols, and also of three abnormal primary alcohols. All the alcohols exhibit a progressive absorption for radiations of short wave-length. The secondary alcohols are slightly more transparent than the normal alcohols with the same carbon content, while the tertiary alcohols are markedly more transparent. Three abnormal primary alcohols, in addition to the normal absorption, show two distinct absorption bands lying at λ 2,500 — 2,700 A and at 3,060 to 3,150 A. These bands are special to the alcohols, and cannot be found either with the fundamental hydrocarbon, with the other alcohols, or with the corresponding alkyl haloids. The corresponding aldehydes present one single broad band coming between the two bands of the alcohols.

Drossbach (Ber. 1902, *35*, 1486) has extended his observations on ultra violet absorption spectra to salts of the rare earths and to several organic liquids. It is found that methyl and ethyl alcohol are completely transparent, while the higher alcohols have a more or less extensive absorption; propyl alcohol being 290; isobutyl alcohol 335; amyl alcohol 332, and allyl alcohol 310. The presence of traces of the higher alcohols in ethyl alcohol can be detected by this means. In the case of the aromatic hydrocarbons, the absorption by benzene is represented by 290; toluene, 288; xylene, 310; m-xylene, 307; mesitylene, 336. The ultra violet absorption very clearly distinguishes between the erbium and didymium groups of elements.

The absorption of ultra violet light by pure acetone has been investigated by *Clarke* and *Stewart* (Physikal. Zeitsch., 1913, *14*, 1049) using layers ranging in thickness from 50 to 400 mm. The curve which is obtained when the wave-length is plotted above λ 332 μμ, although there is a change in the slope of the curve at λ 336.5 μμ. In a note added by Stark it is claimed that this affords clear evidence of the long-wave ultra violet band, the existence of which he has previously anticipated.

Bielecki and Henri (Compt. rend. 1913, 156, 884) made photometric measurements of the spectrographs obtained from a condensed iron-cadmium spark, the light passing through either an aqueous or an alcoholic solution of acetone or through pure acetone, in layers of varying thickness, and determined the values of the molecular constant of absorption, e, in the formula $I=I_0ecd$ for values of λ from 2144 to 3706. The results show that acetone, in solutions, or in the liquid state, possesses only one absorption band in the ultra violet, the maximum being at λ 2706 for alcoholic solutions, and at λ 2648 for aqueous solutions, there being no indication of the second band mentioned by Gelbke. From calculation it is found that about one molecule in forty takes part in the absorption of the ultra violet light by acetone.

The conditions under which a point of inflexion can occur in an absorption spectrum curve have been investigated by *Stark* (Physikal. Zeitsch., 1913, *14*, 845) and it is shown that a point of inflexion in one branch of a band of an absorption boundary or an absorption index-wave-length curve is indicative of the presence of a less intense band in the same wave-length region as the first band. Acetone has a point of inflexion and it is concluded that this body has a less intensive ultra violet band above λ=330 μμ.

Saturated and Unsaturated Ketones and Aldehydes.

According to *Bielecki* and *Henri* (Ber., 1913, 46, 3627) the absorption curves of aliphatic ketones and aldehydes are characterized by an absorption band in the ultraviolet region between 2700 and 2800. The position of the maximum depends on the alkyl group. It is lowest in the simplest aldehydes, and increases regularly with the number of CH_2 groups. In the unsaturated ketones and aldehydes the ethylene linking causes a greater exaltation the nearer it is to the carbonyl. For shorter wave-lengths to the right of the maximum, acetone does not show a minimum until λ=2,144, aldehydes and the more complicated ketones show a minimum, and the absorption curve rises with the complexity of the alkyl. Comparison of the absorption curves of acids, ketones, and aldehydes indicates that the oxygen atom in carbonyl has its partial valencies free, whereas in carbonyl they are united with one another. In the absorption of rays of different wave-length the electrons of sometimes the one and sometimes the other atomic grouping come into play. Only a part of the molecules takes part in the absorption, and this part changes when the wave-length is altered. The ultra violet absorption of fourteen saturated aliphatic ketones has been investigated by *Rice* (Proc. Roy. Soc., 1914 (A), *91*, 76), who shows that the wave-lengths of the centres of the absorption bands depend on the number of methyl groups in the L and B positions relative to the carbonyl groups. Substitution of hydrogen atoms in the λ or further positions has no influence on the position of the band. Rice considers that these measurements show the existence of a relationship between the optical and the chemical properties. The observations are said to be in agreement with the theory that the ultra violet absorption is due to the electro-magnetic field of the carbonyl group as influenced by the substituents in the immediate neighborhood. The ultra violet absorption of a number of ketones has been examined by *Gelbke* (Jahrb. Radioaktiv. Elektronik., 1913, *10*, 1-34; J. Chem. Soc. 1913, Abs., *104*, ii, 87) the substance being dissolved for the most part in ethyl alcohol although in some cases the substances were investigated in the form of saturated vapor or dissolved in water or normal-hexane. From a comparison of the short-waved absorption bands of acetone and its substituted derivatives, it is found that the acetone band, which has its maximum at $\lambda=268$ $\mu\mu$, is displaced in the direction of greater wave-lengths when one or more hydrogen atoms are substituted by alkyl, halogen, phenyl, nitroso or carbonyl groups. In the case of alkyl substitution, the displacement of the maximum amounts to 5 — 10 $\mu\mu$. while the effect of halogens, the phenyl, nitroso and carbonyl groups is greater. The displacement of the band is accompanied by an increase in the absorption and also by a broadening of the band. From a comparison of acetone and cyclohexanone it appears that the influence of ring formation is comparatively small. In addition to the above-mentioned short-waved band, acetone shows a band with a maximum at about $\lambda=326$ $\mu\mu$, which extends from about $\lambda=327$ $\mu\mu$ into the visible spectrum. A similar band is also found in the substituted derivatives of acetone, and it is this which gives rise to the yellow color exhibited by many such substances which contain the carbonyl group. From a comparison of the absorption spectra of dimethyl diketone and methyl ethyl diketone with that of acetone, it is found that the short-waved band in the diketones is shifted about 5 — 10 $\mu\mu$ in the direction of longer wave-lengths, and that the absorption is considerably intensified. In regard to the long-waved band, the shift exhibited by the two a-diketones amounts to about 30 $\mu\mu$ and the intensity is increased about forty times. In the case of B-diketones the intensification of the long-waved absorption band is not nearly so great as that observed for the a-diketones. From a comparison of the spectra of methylheptenone, mesityl oxide, and phorone with that of acetone, it is found that both the short and long-waved bands are not appreciably shifted by a conjugated ethylene linking, although the intensity of the absorption increase vary considerably in both cases. If the ethylene linking is not conjugated, but separated from the carbonyl group by two methylene groups, the intensity of the short-waved band appears to be increased to a much smaller extent than when conjugation occurs.

A large number of substances have been examined in regard to the emission of fluorescent light when subjected to the action of intense utra vio radiation. These observations show that the act ity of the carbonyl group in this direction is qu general, fluorescence being exhibited by both mo and di-ketones, and by both cyclic and acyclic co pounds in which it occurs. It is thus proved t the faculty of fluorescence is by no means confin to ring compounds.

It is suggested by *Henderson* and *Heilbron* (Pr Roy. Soc., 1914, (A), 89, 414; J. Chem. Soc. 191 Abs., 106, ii, 84) that selective absorption of ult violet rays by ketones is caused by intramolecul vibrations due to the alternate formation and brea ing down of unstable ring systems, and that t momentary formation of these is affected throug the agency of free partial valencies which ma their appearance on the atoms of the compou under certain conditions.

In order to ascertain the way in which the absor tion of one chromophoric group is influenced by t presence of another, *Bielecki* and *Henri* (Ber., 191 *47*, 1960) have examined the absorption spect of acetone, dimethyl diketone, ethyl acetyglyoxala and acetonylacetone. Two carbonyl groups in t ∝-position have a hypsochromic action, equivale to about 160 Angstrom units, whereas in the λ po tion they exert only a hyperchromic action. Oth bodies considered are acetic, oxalic and succi acids, allylacetone, methylheptenone, methylis butye ketone, citral, phorone, benzaldehyde, ace phenone, furfuraldehyde and cyclohexanone.

Bielecki and *Henri* (Compt. rend., 1914, *158*, 1,02 have determined the molecular coefficients of sorption between 2,144 and 3,329 of acetone, d cetyl, ethyl diketobutyrate, acetylacetone, meth acetylacetone, and acetonylacetone in solution water, alcohol, dilute acid or alkali, and hexane, a for comparison mesityl oxide, methylhepteno and allylacetone, and from their results have dra the following conclusions. Acetone occurs in very small amount in its enolic form, CH_3.C(OH CH_2, in alkaline solution, the absorption be slightly greater in this medium. The presence a molecule of two carbonyl groups in conjug positions provokes a displacement towards the of the band characteristic of the carbonyl gro thus giving a hypsochrome effect. If the t groups are remote, as in acetonylacetone, there an increase in the absorption, but no displaceme that is, a hyperchrome effect. The absorpt spectrum of a B-diketone varies with the react of the medium and the nature of the solvent, behavior of these substances being explained if th are considered as a mixture of two forms, the p portions of which vary with the solvent.

Bielecki and *Henri* (Compt. rend., 1913, *156*, 1,32 have determined the molecular coefficients of absorpt

Occlusion of Gases

(Continued from page 500.)

by vaporizing some metallic calcium. O. W. Richardson has, however, given evidence in many papers that thermionic emission from heated metals in an intrinsic property of pure metals. Irving Langmuir has made elaborate investigations during the last few years and he concludes that contact potentials of large magnitude do exist even between pure metals in a practically perfect vacuum. The evidence is obtained by the study of (1) electron emission from heated metals (2) photoelectric phenomena (3) contact potentials. Several independent methods lead to values for the contact potentials which are in substantial agreement. This modern work has completely reopened the vexed question of the Volta potential as put forward by Volta himself and supported by Lord Kelvin as a most powerful protagonist: and as opposed by Faraday. Maxwell and the majority of the chemical school with the exception of the chemists in France.

Chinese Wolframite Mines Grow

The deposits of wolframite in South China, according to information in the hands of the Bureau of Domestic and Foreign Commerce, under the pressure of a war made demand have been developed remarkably during the past year. Shipments from Hong Kong alone, not including Swatow, Canton and other points transshipping through Shanghai and other points of transshipment have totaled $1,831,590 gold, so far the current year, the ore generally being valued at $1,000 gold a ton.

According to Chinese reports the industry has reached the dimensions of a veritable boom.

Chemical Warfare Service

Maj.-General Seibert Reviews Work of Service Since Its Inception

HAD the war continued, by next spring America would have deluged the Germany army with poison gas, according to statements made at a dinner given on the evening of December 13 by the commissioned officers of the Chemical Warfare Service to Major General William L. Siebert, director of the service.

Summing up the accomplishments of the service since its inception, General Siebert said in part:

"The Chemical Warfare Service came into existence as such July 13, 1918, by executive order. On Nov. 11 plants for the manufacture of the standard gases were in operation with a manufacturing capacity greater than that of England and France combined, which capacity would have been trebled in the case of certain gases before the beginning of the new year.

"Several other endeavors in the toxic field were just coming into production, and had the war continued until the spring of 1919 we would have subjected the Germans to a deluge of toxic substances such as they never dreamed possible when they commenced this type of warfare.

"This gas production record made by a nation that had not devoted its attention to chemical matters in the past is something to be proud of and something indicative as to the future. Before the war the world looked to Germany in chemical matters, and among the great nations America especially was looked upon as most backward in such matters.

"It is hoped that one of the great results will be to give capital confidence in the ability of our chemical engineers to manufacture chemical substances at a cost that will compete with other nations.

"This war has shown that chemical engineering is the greatest undeveloped field of industry in the United States, and no nation can afford to permit such great possibilities to lie fallow. Our colleges, therefore, should make a specialty of chemical engineering."

Col. W. H. Walker, chief of the Gas Production Branch of the Service, told of the gasses made at the Edgewood arsenal. At the time the armistice had been signed shiploads of gas-loaded shells were going to Europe and hundreds of containers of gas were being piled up.

Col. Bradley Dewey, in charge of the production of gas masks, said that a gas mask had been evolved without nose or mouthpiece. A man could wear it indefinitely.

Mr. T. A. Lawton, 17 Battery Place, New York City, has been appointed New York representative of the American Creosoting Company

INCORPORATIONS

THE coming of peace has apparently had little effect on the formation of new corporations chartered to manufacture chemicals and allied products. Reports from the capitals of the various states would serve to indicate that capital seeking investment retains its faith in the future possibilities of the chemical industries of this country.

DELAWARE

The Washington Dye and Chemical Corporation has been incorporated under the laws of Delaware with an authorized capital of $150,000. The incorporators are O. J. Ricketts, J. D. Hird, and George T. Parker, all of Washington, D. C.

Maree-Roze Manufacturing Company, Wilmington, Delaware, has been incorporated with an authorized capital of $100,000 and will carry on the business of soap manufacturing.

The Prockter-Price Soap Company, of Dover, Delaware, has been incorporated with an authorized capital of $75,000. The new corporation will manufacture soaps and toilet articles of all kinds.

The St. Jacobs Oil Co. has been incorporated in Delaware with a capital of $300,000.

The American Potash and Nitrate Corporation has been formed under the laws of Delaware with a capitalization of $500,000. Incorporators: Robert Hobart, C. Fash, James F. Starck, Elisha W. Keely, of New York.

The Walter Luther Dodge Co., drugs, chemicals, etc., has been incorporated under the laws of Delaware with a capital of $320,000.

The Republic Match Company has been incorporated under the laws of Delaware with a capital of $40,000.

Kali Company of America, potash, etc., has been incorporated under the laws of Delaware with a capital of $1,000,000. Incorporators: Stuart H. McIntosh, Joseph W. Henry, Thomas Robinson, all of New York.

The Sun Chemical and Color Company, of Wilmington, Delaware, has been incorporated with a capital of $100,000. The new firm will manufacture paints, dry colors and stains and similar materials.

The Pauver Company, manufacturers of chemical products, have been incorporated under the laws of Delaware with a capital of $10,000. The incorporators are M. A. Meyrcord, John E. Fleming and Ira G. Ross, all of Philadelphia

MAINE

The Abbott Chemical Company has been organized under the laws of the State of Maine, with an authorized capital of $50,000. The new company, which is headed by Mr M F Hearin, of Augusta, Me., will take over and conduct the business of the Abbott Chemical Company and the Abbott Marshall Company.

NEW JERSEY

The Keystone Solether Corporation, of Trenton, New Jersey, has been incorporated with a capital of $250,000 to manufacture synthetic and artificial leathers, floor coverings, etc.

Acme Graphite Mining Co., of Westfield, N. J., has been incorporated with a capital of $100,000. Incorporators: W. M. Hoag, of Westfield, and George C. Angel and A. S. Sayes, of New York city.

The Kinsey Chemical Company, of Jersey City, New Jersey, has been incorporated with a capital of $100,000 to manufacture chemicals.

NEW YORK

The North American Industrial Transatlantic, Inc., Manhattan, has been incorporated with an authorized capital of $50,000. The company will manufacture dyestuffs. The incorporators are R. Illowy, E. M. Waldo, A. Gabriel, all of 670 Sixth avenue.

Proco Chemical Company, of Manhattan, has been incorporated by P. Webb, M. and C. H. Brown, 2043 Bathgate avenue, Bronx.

J. F. Chapman & Co., of Manhattan, acids, chemicals, etc., have been incorporated with 100 shares of preferred stock, par value $100, and five shares common stock, no par value; active capital, $75,240.

American Nitration Company, of Newark, N. J., has been incorporated with a capital of $50,000 to deal in alkalies, chemicals, etc. The incorporators are D. L. Summey, Waterbury, Conn.; Alfred Weeks, Nutley; William A. Wachenfield, of Newark, N. J.

The Fatty Acid Reduction Company, of Syracuse, has been incorporated with a capital of $200,000.

The St. Regis Falls Wood Corporation, of Watertown, N. Y., makers of pulp and wood products, has been incorporated with an authorized capital of $30,000. The incorporators are F. L. Carlisle, B. G. Martin and R. K. Ferguson, all of Watertown.

American Drying Process, Inc., of Manhattan, chemical preparations, etc., has been formed under the laws of this State with a capital of $10,000. Incorporators: E. A. Zema, T. A. McCarthy, W. F. Delaney, 20 Vesey street.

The Post South Sales Company, of Buffalo, has been incorporated with an authorized capital of $10,000 to handle chemicals and allied products.

The Nico Chemical Corporation, of Manhattan, has been incorporated with an authorized capital of $100,000 to manufacture potash, explosives, dyes and chemicals. The incorporators are J. T. Fenlon, 169 Secor street, Pelham; S. Klein, 55 Liberty street, New York City, and H. L. Schaefer, Sea Cliff, N. J.

Berner-Geiger, Inc., of Queens, drugs, chemicals, etc., has been incorporated under the laws of New York with a capital of $10,000. Incorporators: J. Geiger, I. M. Schwartz, N. Berner, 130 Rivington street.

PENNSYLVANIA

The Standard Chemical Company, of Reading, Pa., has been incorporated with a capital of $100,000. Jacob H. Reichert is the president of the new corporation.

TEXAS

The Purity Serum Company, of Fort Worth, Texas, has been incorporated with an authorized capital of $150,000. John Kennedy is the president of the new firm.

VIRGINIA

The Cumberland Chemical Company capitalized at $100,000 has been chartered at Bristol, Virginia. E. W. Pendleton is president of the new company and E. R. Levy, of New York City, the secretary-treasurer. The firm will have a New York office.

Mesothorium Radium Substitute

Welsbach Company Now Turning Out Mineral in Large Quantities

THE increasing demand for radium for medical work, but more particularly for luminous paint, has made the quesion of possible radium substitutes of considerable importance. Radium luminous paint has been used in the war for a number of purposes, more particularly on the dials of instruments used on airplanes, so that these instruments can be read at night; for electric push buttons, door numbers and small images for shrines, etc. The paint is permanently luminous in the dark and contains from 0.1 to 0.25 milligrams radium element to one gram of zinc sulphide. A luminous watch face usually has from ten cents to twenty cents of radium on it.

An excellent substitute for radium for certain purposes is meso-thorium. This is a radio-active element found in monazite sand and other thorium minerals. When first extracted it is not in a satisfactory condition for luminous paint, but must be allowed to "ripen" for several months or even a year before it can be used. During this time the Alpha radiation which is required for luminous paint becomes sufficiently strong. On the other hand the beta and gamma radiation of meso-thorium grows rapidly and it can be used for medical purposes within a few days after preparation.

Radium has a long life, half of it decaying in approximately 1600 years. Meso-thorium on the other hand has a short life, 5 or 6 years being its useful life for luminous paint purposes. The price in the past has varied from 40 to 60 per cent. of that of radium, the comparison being on products of equal activity. For medical purposes, therefore, it cannot compete with radium as long as there is plenty of the latter; for luminous paint, to be used on objects which themselves have a short life, it is an excellent substitute for radium and will tend towards the saving of radium for medical purposes.

It undoubtedly has been used during the war especially by the Germans. Some of the first luminous watch dials in this country probably contained meso-thorium imported from Europe.

Until recently no meso-thorium was recovered in the United States, although large quantities of monazite sand are annually treated for the manufacture of incandescent gas mantels. Such a condition has represented an important mineral waste.

Shortly after the United States entered the war the Bureau of Mines made a co-operative agreement with the Welsbach Company of Gloucester, N. J., for the study of methods of extraction and recovery of meso-thorium. The work was carried on at the Rocky Mountain station of the Bureau of Mines at Golden, Colo., under the direction of Dr. R. B. Moore, Superintendent of the station, Dr. Herman Schlundt being assigned to the detailed work on the problem. Successful methods of extraction and recovery have been worked out and connected up with the regular metallurgical processes of the Welsbach Company. Meso-thorium is now one of the regular products made by this company. The next largest producers of thorium salts in the country about the same time became interested in the recovery of meso-thorium and worked out its own methods. Consequently at the present time meso-thorium is recovered from practically all the monazite sand treated in the United States.

The details of the work of the Bureau of Mines will be published later. A preliminary announcement was made by Dr. Moore in a paper given at the September meeting of the American Institute of Mining Engineers at Colorado Springs.

The Bureau of Mines has never claimed the discovery of meso-thorium as this element was first identified and described by Hahn in 1905.

Census of Research Laboratories

With a view to ascertaining the location and resources of all laboratories in the United States capable of being used in industrial research work, Mr. Alfred D. Flinn, secretary of the Engineering Foundation, is seeking all available information regarding them on behalf of the joint committee of the Engineering Foundation and National Research Council on Promotion of Industrial Research. Readers of The Chemical Engineer having laboratories not already listed by The Engineering Foundation are asked as a patriotic duty to communicate with Mr. Flinn at 33 West Thirty-ninth Street, New York City.

The Home Market Club of Boston, of which Thomas O. Marvin is secretary, at its annual meeting held recently, placed itself on record as opposed in the most emphatic way to the importation of German made goods in the United States after the signing of the final peace treaty.

The Club further stated its belief that American industries should use American dyes and that the Government should protect the American dyestuff and chemical industries by an adequate tariff and other means of regulation.

The results of the labors of the staff which under the guidance of Dr. F. R. Pickerell, chief chemist of the United States appraisers' stores of the port of New York, have been engaged in compiling a census of the chemical imports during the fiscal year, will, according to the Commerce Reports of the Bureau of Foreign and Domestic Commerce, shortly be ready for publication. According to this authority, this census has been a tremendous undertaking as over 20,000 invoices of chemical imports had to be segregated from invoices of general imports.

Using Many Substitutes

British Make Successful Use of New Paper Materials

SCARCITY of raw materials, due primarily to war conditions, has affected a wide use of substitute materials in all parts of Great Britain.

In this substitution program paper has paid a very important part. It has been found particularly useful as a substitute for jute. India, England's only source of jute, was several thousand miles away and shipping had, due to the exigencies of war, to be materially curtailed. While the supply of jute had to be cut radically there was simulataneously an equally abnormal demand from those articles in whose manufacture jute is principally used.

Thanks to the fact that efficient machinery for the manufacture of paper textiles developed in Great Britain before the war broke, the industries of the country were able to rise, without a great deal of difficulty to the emergency.

Today paper bags are being used as containers for potatoes, seed, fertilizer, coffee, sugar and grain. In appearance and quality these paper bags are not unlike the jute article but with the advantage that as in the case of the burlap article there are no loose fibres to mix with the contents of the containers. While the new bags cannot of course be moved about by means of hooks as are the burlap article, this difficulty has been surmounted by the placing of lugs on the corners of the bags.

Today an extensive use is also being made in Great Britain of paper as a substitute material in the packing of biscuits, jams and other food products and a paper substitute for window glass has been perfected that has met with much favor in the army huts in France.

Thanks to the fact that there has not been any serious shortage of cotton and wool in Great Britain during the war, the making of paper textiles for clothing has not been developed to the extent it has in Germany. So far only vests, sou' westers, capes and waders have been made of paper materials in this country.

English manufacturers are not inclined to believe that the paper textile industry will threaten to any serious extent the stability of the true textile industry in the near future. While the substitution of paper textiles for the real articles have played no small part in the successful prosecution of the war, it seems hardly likely that paper textiles will replace anything but a certain proportion of jute and hemp.

Taylor, Lowenstein & Co., of Citronelle, Ala., have purchased 800 acres of timber land and will extract turpentine

To Make Caustic in Brazil

American Corporation Buys Site Near Santos—Mill to Cost $500,000

AN American company is to erect a factory in Brazil for the manufacture of caustic soda and other chemicals, according to consular reports from Rio de Janeiro. The company has already purchased 720,000 square meters of land near the city of Santos.

The total capital involved is said to be about $500,000, of which 50 per cent. is to be raised locally and the other 50 per cent. furnished by the company in the United States which is to supply the necessary machinery. The proposal of the government of Sao Paulo states that the company will build the necessary facilities for the manufacture of caustic soda, consisting of twelve buildings measuring between 90 and 2,300 square meters each, an administration building, houses for workmen, night schools for children, and an industrial school for the adult laborers, all these buildings to be built according to modern industrial and hygienic plans.

The factory under full operation is estimated to produce daily 15 tons of caustic soda, 15 tons of chloride of lime, 600 kilos of muriatic acid, and 600 kilos of chlorate of potash. In these operations the company will use each day 25 tons of salt, 10 tons of lime, 400 kilos of muriate of potash, and 3 tons of charcoal.

Want German Patents

E. I. du Pont de Nemours Apply for German Dye Stuff Rights

The E. I. Du Pont De Nemours & Company, Wilmington, Delaware, asked the Federal Trade Commission for licenses to use German-owned or controlled patents covering acids, dyes and processes for making them.

At the same time, E. C. Klipstein & Sons Company, New York City, asked for license to use a patent for "The Process of Bating Hides"; and the Phenarsenyl Distributing Company of New York, Inc., applied for two licenses covering acids manufacture.

The patents were issued by the U. S. Patent office at various times from 1909 to 1914, to German firms or their assignors of Darmstadt, Frankfort-on-the-Main, Offenbach-on-the-Main, and Ludwigshafen-on-theRhine, Germany.

The Du Pont license applications are for use of patents on the following: "Producing Ice Colors," "Stable Indigo-White and Process of Making Same," "Compounds of Leuco Vat Dyes With Aralkyl Compounds and Process of Making Same," "Reducing Indigo Coloring-Matters," "Aromatic Ammonium Compounds and Process of Making Same," "Azo Dyes from the Arylamids of 2.3-Oxynaphthoic Acid and Process of Making Them," and "Condensation Products from the Arylamids of 2.3-Oxynaphthoic Acid and Formaldehyde and Azo Dyestuffs Therefrom and Process of Making Same."

The picric acid plant now in course of construction in North Brunswick, Georgia, will be completed, according to Washington reports, and will be used to manufacture dyestuffs, fertilizer and other byproducts of the process of picric acid manufacture.

Manufacture of Straw Paper

Will Growing Scarcity of Wood Revive Industry?

THE recent prophecy on the part of an old-time paper manufacturer, that the growing scarcity of soft woods in the United States would result eventually in a revival of the American straw paper industry, sounds interesting in these days when ways and means of handling by-products and substitutes of various kinds is so much to the fore. The last straw paper mill in the United States closed its doors in 1903. The principal cause of the decline of the industry was the competition of wood pulp paper and the invention of the various devices for the turning out of cheap paper. The causes which would possibly put it on its feet again would be a continued rise in the cost of the wood pulp product, a continued rise which is well within the realm of possibility, in these days of high prices and raw material scarcity. Further, large supplies of the fibre from which straw paper is made can be raised on the land annually, while it takes many years to replace a tree.

Previous to the Civil War all the newspapers of the country were printed on straw paper, and at one time there were as many as sixty plants making this kind of paper. It is well within the memory of most people now living, when brown straw wrapping paper was to be found on the counters of most of the stores in the country. Today this product would be a curosity if it were encountered.

Old-Time Paper Making.

In those days the process of paper making was a rather slow and cumbersome business. To make paper this pulp was floated in vats, at the side of which stood the workmen, mould in hand. This mould was of wire cloth, around the outer edges of which a rim was formed by superimposing a thin frame called a "deckle," which prevented the pulp from flowing off and left the water no other escape than through the bottom of the mould. Into this the pulp was dipped and as the water drained away the pulp was left in the form of a thin layer covering the bottom of the mould. At this point it was given to another man—a workman known as the "coucher"—whose duty it was to remove the mould. This was done by the application of a piece of felt to which the pulp adhered in the form of a thin sheet. A second piece of felt was then placed on top of this and to this felt another pulp mould was applied, and this process was continued until the pile of alternate layers of pulp and felt had attained the requisite height.

Method of Drying.

From this pile, or "post," as it was called, all the water was thoroughly expressed and the pulp, separated from the felt, was pressed and hung upon the "tribbles," or lines in the drying room. This portion of the process completed, the sheets were still rough and somewhat like blotting paper, so it was necessary to dip them in size and to press and dry them again before they assumed the character of a finished product.

Paper making is one of the oldest of the American industries. As early as 1690 William Rittenhuysen, an experienced paper maker from Holland, in partnership with William Bradford, a Philadelphia printer, opened the first paper mill ever established on American soil. It was located on a stream since known as Paper Mill Run, near Philadelphia. and there a fair quality of paper was manufactured out of the rags of the home-grown flax. Of course, the method was very primitive, and it was not until 1756 that the first pulp engine to be introduced in this country was imported from Holland.

In 1794 a large paper mill was established at Troy by Websters, Ensign & Seymour, and during the same year a mill for the manufacture of coarse wrapping paper from the bark of the basswood tree was opened at Fairhaven, Vt., by Matthew Lyon. As this was the first establishment in the United States to attempt to make use of anything except rags for pulp, the enterprise attracted no little attention.

Coming of Straw Paper.

The general use of straw paper began in 1857. Some three years previous to that time a Frenchman named A. C. Mellier had succeeded in converting several vegetable fibres, notably straw, into pulp, which he believed would be suitable for use in the manufacture of paper. The process, which has since borne his name, was neither a difficult nor costly one. The straw was first thoroughly soaked and after it had been cleaned it was boiled at a temperature of not less than 310 degrees Fahrenheit, in a solution of about 4 per cent. of caustic soda. Although, Mellier peddled his idea from one end of the country to the other, the big manufacturers of paper did not seem to consider the scheme a practicable one, and three years, therefore, elapsed before he was able to persuade anybody to invest money in his project.

The man who finally undertook to make paper by this process was J. B. Palser, a member of the firm of Howard & Palser, and the factory they established at Fort Edward, N. Y., for the express purpose of carrying Mellier's idea into effect, proved an excellent investment.

A fish fertilizer factory is to be built at Morehead Bay, N. C. The new plant when completed will have a capacity of 50,000 fish an hour.

Chemical Exports Increase

Since Opening of 1914 U. S. Exports Have Increased Over 600 Per Cent.

Since the outbreak of the war in Europe, the annual exportation of chemicals from the United States has increased over 648 per cent. In the year preceding the war the exports totalled $27,000,000; in the year which ends with the current month the exports will total $175,000,000.

A compilation by the National City Bank of New York shows that the value of chemicals exported steadily grew from the beginning of the war, and, as above indicated, will approximate $175,000,000 in the current year, against about $27,000,000 in the year immediately preceding the war.

The United States has always been a large importer of chemicals, the total value of this class of merchandise imported prior to the war being about three, and in some instances as much as four times the exports, and while the demands of the war have been such as to somewhat stimulate the importation, meantime the percentage in the growth in imports has been small compared with the percentage of growth in exports. The imports grouped under the head of chemicals consist largely of classes of materials not produced in the United States, and included in the fiscal year 1918, $70,000,000 worth of nitrate of soda, a Chilian product, and $22,000,000 worth of gums, strictly tropical products.

Eliminating these strictly tropical article which have been classed by the Government of "Chemicals," the present importation of manufactured chemicals is extremely small, indicating that our own manufacturers are at present supplying the great markets for chemicals in the United States, and at the same time sending nearly $150,000,000 worth a year to foreign markets. In the full fiscal year 1918 the chemicals exported aggregated in value $152,000,000, against $27,000,000 in the year preceding the war, $46,000,000 in the first year of the war and $124,000,000 in the second year of the war.

Dyestuffs and Dyes.

The most striking feature of this growth in the exportation of chemicals occurs in dyes and dyestuffs, of which the United States was, prior to the war, an extremely small exporter and a very large importer. The total value of dyestuffs exported in the fiscal year 1918 was $17,000,000, against $12,000,000 in 1917, $5,000,000 in 1916, $1,000,000 in 1915 and less than $500,000 in 1914, the year preceding the war. Prior to the war the exportation of dyes and dyestuffs had never exceeded about $500,000, while imports of dyestuffs prior to the war aggregated from $10,000,000 to $15,000,000 per annum.

Dyestuffs exported to Great Britain in the fiscal year 1918 total over $2,500,000, against $70,000 in the year before the war; to France, $1,630,000 worth, against $2,000 in the year preceding the war; to Italy, $1,182,000 worth, against $11,000 in 1914; to Japan, $3,233,000 worth, against nothing in 1914; to India, $1,948,000, against $93 worth in 1914, and to Brazil, $1,282,000 worth, against $65 in 1914.

Exports of chemicals from the United States in the nine months ending September, 1918, compared with the fiscal year 1914, were as follows:

	1914.	1918.
Acid, carbolic	No data	$1,284,000
Picric	No data	22,275,000
Sulphuric	$126,000	993,000
Other acids	357,000	3,189,000
Alcohol, wood	652,000	1,856,000
Baking powder	790,000	1,177,000
Calcium carbide	962,000	1,079,000
Coal tar distillates	No data	6,480,000
Copper sulphate	330,000	1,210,000
Aniline dyes	No data	5,773,000
Logwood extract	No data	1,312,000
Other dyes and dyestuffs	357,000	4,703,000
Tanning extracts	640,000	2,469,000
Formaldehyde	No data	653,000
Glycerin	No data	7,029,000
Medicinal preparations	6,722,000	7,733,000
Petroleum jelly	662,000	971,000
Potash	No data	880,000
Roots and herbs	513,000	1,520,000
Soda, caustic	No data	4,493,000
Ash	No data	5,184,000
Other salts	No data	5,775,000
Sulphur	2,019,000	2,788,000
Other chemicals	12,948,000	35,388,000
Total	$27,079,000	$126,214,000

Exports of dyes and dyestuffs from the United States for nine months ending September, 1918, compared with the fiscal year 1914, were as follows:

	1914.	1918.
France	$2,000	$560,000
Italy	11,000	530,000
Russia in Europe	3,000	13,000
Spain	......	840,000
United iKngdom	70,000	1,103,000
Canada	129,000	1,012,000
Mexico	1,000	305,000
Argentina	......	567,000
Brazil	65	1,139,000
Chile	1,000	140,000
British India	93	1,003,000
Japan	......	3,319,000
Other countries	140,000	1,258,000
Total	$357,000	$11,788,000

At the annual meeting of the New York Academy of Sciences, held on the evening of December 16, in the Museum of Natural History, all the officers of the organization were reelected as follows: Ernest E. Smith, president; Edmond O. Hovey, Frank H. Pike, George B. Pegram, Pliny E. Goddard, vice-presidents; Ralph W. Tower, recording secretary; Henry E. Crampton, corresponding secretary, and John Tatlock, treasurer.

DU PONT AMERICAN INDUSTRIES

DU PONT DYESTUFFS

What the Ending of the War Means to Our Industry

For more than four years the manufacturing powers of our industries have been almost entirely absorbed in meeting the demand for munitions of war.

As the world's largest manufacturers of explosives our responsibilities have been great—how great may be judged when it is known that since the outbreak of the war—a war in which the quantity of men, munitions and equipment employed, staggers the imagination—we have been the principal source of explosives not only for this country but for our allies.

With the ending of the war that task is done. From now on our entire resources—men, capital and manufacturing facilities—will be devoted to the making of munitions of peace—to the greater task of winning for America's industries a foremost place in the world reconstruction era that is now beginning.

In our dyestuffs industry, the release of labor from our munitions plants, the availability of men trained in the closely allied explosives industry, hitherto unavailable supplies of crudes and intermediates and the possibility of needed extensions in our plant facilities, assure from now on rapid and satisfactory development.

Du Pont Dyestuffs Works

Owned and Operated by E. I. du Pont de Nemours & Co.

OWN and OFFER

DRYERS

2—5'6"x40' direct heat rotary dryers—complete.
1—3'x30' direct heat rotary dryer—complete, with stack.
1—4'x21' Type B double shell Ruggles-Coles dryer.
1—5'x20' Louisville rotary steam heated dryer.
1—72" Ord Standard cooker or dryer, agitated and jacketed.
1—Buffalo vacuum shelf dryer, 11 shelves—complete, with jet condenser and vacuum pump.

PRESSES

3—30" Schriver, 36 plates, 1" cake, center feed.
1—36" Shriver, 42 plates, 1" cake, center feed.
1—3'x4' Type 84M Oliver filter, with receiver, pump, etc.
10—Smith-Vail 15 and 16 box hydraulic presses.

KETTLES

2—5'3"x4' new Buffalo cast iron fusion kettles—complete.
2—4'x5'6" 5/16" steel open top jacketed agitated kettles.
2—6'x10'6" ½" steel cone bottom, closed tanks, with manhole and bottom drop door.
1—4'x7' ⅜" steel, flat bottom, closed tank, manhole, etc., upright.
1—6'x3' open top, round bottom cast iron kettle.
1—32-gallon Pfaudler enameled kettle, agitated.
1—50-gallon Elyria enameled kettle, agitated and jacketed.

KILNS

1—5'x48' rotary kiln, fire brick lining, and castings.
1—5'6"x50' rotary kiln, fire brick lining, and castings.
3—6'x60' rotary kiln, fire brick lining, and castings.

MILLS

1—48"x10' tube mill—Silex lined, pebbles, automatic feeder.
1—44"x25' tube mill—Silex lined, pebbles, automatic feeder.
1—2'6"x1'11" Abbe pebble mill, porcelain lined, with A. C. motor.
1—22"x6' Hardinge conical mill—stone lined, automatic feeder.
1—24" Schultz-O'Neill pulverizer, with dust collector.

STILLS

1—400-gallon Pfaudler enameled stills.
1—200-gallon Elyria enameled still.
1—3'x26' six-section copper still, with condenser and delegmator.
1—5'6" diameter, 28-chamber rectifying column still and kettle—complete, all copper.

TANKS

2—12'x10'x8' deep ¼" square iron tanks.
4—12'x12'x6'4" deep ¼" square iron tanks.
2—12'x12'x8' deep ¼" square iron tanks.
2—10'x10'x7' deep ¼" square iron tanks.

MISCELLANEOUS

1—1½" Gould Triplex plunger pump—bronze fitted.
1—2" Gould centrifugal pump.
1—2" Lawrence two-stage centrifugal pump.
1—2" rotary pump, direct connected to 5-H.P. D. C. motor.
1—No. 4 Figure 198 Rumsey power rotary force pump.
1—24" exhaust fan, with Westinghouse 2-phase, 60-cycle, 220-volt motor.

Fuller description furnished upon request. Always interested in the purchase of Chemical Apparatus.

POSITION WANTED—Three years in chemicals and colors, buying, selling, office work. C. J., c/o CHEMICAL ENGINEER.

CHEMIST—Graduate New York College Pharmacy, part time at Pratt Institute, 16 years' experience in compounding as druggist, desires position requiring knowledge of compounding and analysis. Mehler, 1767 Southern Boulevard, New York.

British Sulphuric Acid Substitutes

One of the largest and most striking economies in the consumption of acid introduced by the Acids Supply Branch of the British Ministry of Munitions has been the industrial utilization of waste products as substitutes for sulphuric acid. The principal of these substitutes is niter cake, a waste product from the manufacturer of nitric acid. Niter cake is produced at the rate of about 28,000 long tons per month, and toward the end of 1915 practically the whole production (then on a smaller scale) was being thrown away—in some cases at a cost of £1 per ton for discharging into the sea or dumping on land. Taking advantage of the control of sulphuric acid, the Acids Branch introduced the industrial use of niter cake into all trades where sulphuric acid performs a somewhat crude function—such as in the textile and dyeing trade, grease recovery, and metal picking. The market price of niter cake consequently rose considerably, and at the present time some 23,000 tons per month are being consumed in about twenty five different trades.

Production of Sulphuric

Arthur E. Wells Estimates Production at 6,300,000 Tons in 1919

THE production of sulphuric acid during 1919 will be about 6,300,000 tons a year, according to estimates prepared for the Bureau of Mines, by Mr. Arthur E. Wells, the metallurgist on the staff of the Bureau. Mr. Wells estimates that the consumption will be in the neighborhood of 4,600,000 tons per year.

Mr. Wells' report reads as follows:

On January 1 of this year the total manufacturing capacity of the country for acid was 427,000 tons per month, (basis 100% H_2SO_4), or 8,200,000 tons per year, basis 50° Be), of which 29% was at contact acid plants.

On November 1 of this year the total manufacturing capacity of the country was 500,000 tons per month, (basis 100% H_2SO_4), or 9,600,000 tons per year, (basis 50° Be.) Of this total capacity 40% was at contact acid plants.

This capacity was divided among (1) Government, (2) explosives companies, (3) all others, including commercial manufacturers, by-product manufacturers, etc., as follows:

	Capacity	
	Expressed as tons per month 100% H_2SO_4	Expressed as tons per year 50° Be.
(1) At Government plants	54,000	1,040,000
(2) At plants of explosives manufacturers	58,000	1,120,000
(3) All others	388,000	7,440,000
	500,000	9,600,000

Inasmuch as the acid market conditions in the inter-mountain and Pacific coast districts are quite distinct from those in the East, and as there has been brought about very little, if any, disturbance in those districts, except for possibly some slight disturbance in the San Francisco district, it is not necessary to include the figures for those districts in the discussions regarding Eastern conditions.

The total capacity east of the Mississippi River, and also including the plant at Argentine, Kansas, and the plants in Louisiana and Arkansas, is as follows:

	Tons per month as 100% H_2SO_4
(1) At Government plants	54,000
(2) At plants of explosives companies	50,000
(3) All others	350,000
Total	454,000

If we assume that the Government plants and the contact plants which were built by the explosives companies primarily to supply acid for munitions explosives, are not operated in 1919, or if operated at all, the production will be utilized only for munitions and thus will not be placed on the market, there remains a total capacity to be considered in the eastern part of the United States amounting to 365,000 tons per month (basis 100% H_2SO_4) or 7,000,000 tons per year, (basis 50° Be).

During the months June, July, and August, 1918, the following industries in the eastern part of the United States consumed approximately the following tonnages of acid:

Industries	Tons per month Basis 100% H_2SO_4
1. Domestic explosives	7,500
2. Fertilizers	109,400
3. Chemicals and drugs, including nitric acid, hydrochloric acid, ammonium sulphate	37,600
4. Oil refining	28,700
5. Steel pickling and galvanizing	36,200
6. Fabrics, textiles, tanning, rubber, paper bleaching	5,100
7. Paints, lithopone, dyes, glue, glycerine, alcohol	7,200
8. Storage batteries, metallurgical work	4,700
9. Miscellaneous and unknown	3,600
Total	240,000

or 4,600,000 tons per year (basis 50° Be).

It is believed that the consumption of acid in the various industries during the period as given above offers a better basis for estimating the future consumption during 1919 than any reference to the figures of 1914. However, it may be stated by way of comparison that in the eastern half of the United States there were consumed in 1914 about 3,500,000 tons of acid (basis 50° Be), according to the figures compiled by the U. S. Geological Survey. From these figures it is evident that between the years 1914 and 1918 there was an increase in the requirements of acid for industries, other than munitions explosives, amounting to about 1,000,000 tons (basis 50° Be). The consumption of acid for fertilizers will undoubtedly be greater in 1919 than in 1918, and will probably average at least 130,000 tons per month (basis 100% H_2SO_4), or 2,500,000 tons per year (basis 50° Be). Thus, with general business conditions favorable, the average monthly consumption of acid in the above industries in the eastern part of the country during the year 1919 should not be less than 260,000 tons per month (basis 100% H_2SO_4), or 5,000,000 tons per year (basis 50° Be). This would require operating all the plants at about 71% of the rated maximum capacity, if the business was distributed over the district proportionately to the manufacturing capacity in the various districts. As a matter of fact, the southern fertilizer plants will probably operate to full capacity, while plants in the Boston, New York, Philadelphia and Baltimore districts may have to average less than 70% of the rated capacity.

The production and consumption of acid in the western half of the United States will probably be about 500,000 tons per year (basis 50° Be), so that the probable total production for the whole country will be about 5,500,000 tons in 1919.

ULTRA VIOLET LIGHT

(Continued from page 506)

and the positions of the maximum and minimum absorption of a number of aliphatic ketones and diketones and ketonic acids, and from their results have drawn the following conclusions. All substances having the general formula $C_nH_{2n}+_1 \cdot CO \cdot C_mH_{2m}+_1$, have an absorption band between λ+2,700 and 2,800, the position and height of the band varying but little with m and n. The method of linking in the alkyl radicles and the position of the ketonic group have a market effect on the value of the coefficient of absorption. The introduction of a second ketone group into the molecule increases the absorption, without altering the position of the maximum. The introduction of the carboxyl group into a ketone has a double effect in that the absorption due to the carboxyl group increased, while that of the ketone group is diminished.

A number of photochemical reactions have been examined by *Henri* and *Wurmser* (Compt. rend., 1913, 156, 230) to see whether Grotthus's law of photochemical absorption, that the photochemical susceptibility is proportional to the absorption, holds good in all cases. For acetone and ethyl acetate the maximum decomposition corresponds with the region of maximum absorption. In the case of acetaldehyde the absorption curve presents a maximum at λ 2,775, then diminishes to a minimum and finally increases steadily for the extreme ultra violet rays, while the decomposition is a maximum at λ = 2,775, and then diminishes, showing no minimum, and being very feeble in the extreme rays. The conclusion is reached that the susceptibility of a substance depends only on that part of the absorption spectrum which corresponds with the same molecular grouping as those on which the action is produced.

Magini (Atti. R. Accad. Lincei, 1904, (v) 13, i, 104; J. Chem. Soc. 1904, Abs., 86, ii, 305) examined the ultra violet absorption of two samples of ethyl acetoacetate, one of which was stated by Schiff to be the pure enolic modification, and the other to consist of about an equal proportion of the enolic and keto-forms. The differences between the two spectra are very slight, as also are those produced by distilling the liquids and do not admit of any conclusion being drawn as to the existence of keto- and enolic modifications ethyl acetoacetate. *Bielecki* and *Henri* (Compt. rend., 1914, *158*, 866) have made a quantitative examination of the absorption spectra in the ultra violet of ethyl and methyl acetoacetates, and ethyl ethylacetoacetate and diethylacetoacetate and substances having allied structures, namely, ethyl crotonate, mesityl oxide, pyruvic acid, ethyl puruvate, and ethyl laevulate.

W. L. Schultz has been appointed New York representative for Roxey, Inc., a Delaware corporation making soap, soap powder and similar products.

available in your own Laboratory

Every Chemical Laboratory should be equipped with a source of Ultra Violet Rays.

The R. U. V. Ultra Violet Ray Lamp is especially recommended to those chemists who have failed to get desired results with the ordinary form of lamp.

POINTS OF SUPERIORITY OF R. U. V.

As an indication of its superiority, it has been proven that the R. U. V. Lamp yields twice the usual ultra violet component.

The increased radiation insures rapid developments of possible reactions.

The lamp is adaptable to various kinds of vessels. High efficiency is assured by manufacture of frame from new and clear quartz exclusively.

There is perfect electrical control.

THE R. U. V. CO., Inc.

Bureau of Mines Report

Director Manning's Report Tells of War Activities of Bureau

HOW a great governmental agency engaged in saving the lives of miners and promoting the welfare of the industry, at the call to arms was instantly turned into an engine of death and destruction to enemies, is detailed in the annual report of the Bureau of Mines, Department of the Interior, by Van H. Manning, the director.

The report, which closes with the fiscal year June 30, while the United States was still at war, tells of the strenuous part played by the Bureau of Mines in assisting to build up the terrifying machine of death that would not have been felt with its fullest force by the Hun until the following spring. With the cessation of war the Germans, it is said, will never be able to realize what the full force of America's military might would have been, or the many devices and methods that were the result of American ingenuity, for the War Department is keeping the best of these a profound secret.

At the same time great good for the future peaceful pursuit of industry in this country and for the saving instead of killing of men has come out of this welter of death-dealing experiments, is the claim of the Bureau of Mines. Certain experiments with delicate instruments known as microphones and geophones, in order to detect the direction and the distance of enemy mining work in tunneling and the location of enemy artillery no matter where placed, has disclosed that these same instruments can be of use in determining the location of men entombed in mines following disaster. It is expected that, if the men have the presence of mind to make even a slight noise, the rescuers listening with these devices will be able at once to locate the men and begin the rescue work. Men thus entombed have been known to live for a week or longer under such circumstances, the rescuers being unable to find them. Other men have died before they could be located. The bureau will equip its rescue cars as soon as possible with these devices.

The war experience of the bureau is going to help peace industries in still another direction. The coal experts, eager to do their share in winning the war, were assigned to the testing of boilers to be used in the ships of the Emergency Fleet Corporation. Speed and the saving of coal were demanded. The result was that the experts so changed the design of the boilers that the coal heretofore necessary to send the ships along for six miles was sufficient to carry them seven miles. This great saving will be available in peace times.

Early in the war every experiment station of the bureau in the mining districts of the country at once closed its peace activities and marshalled for war. The entire bureau and its men and equipment were offered to the two war services. Especially pressing scientific problems were allotted to the different stations, and where the bureau did not have all the men necessary, it turned over its laboratories and equipment to the men assigned by the War and Navy Departments. In this way a central-control laboratory for the testing of materials of war was established at the Pittsburgh station of the bureau by the Ordnance Department. Steel for cannon, material for cartridges and other materials used by the Ordnance were here tested for flaws and weaknesses. The War Department was determined that no soldier, in the emergency of battle, would be able to say that his gun failed him because of faulty material.

The War Department next seized upon the opportunity of using the bureau's explosives station and bomb-proof a few miles from Pittsburgh and there many important, yet secret tests into the action of new and deadly explosives, were made under the supervision of the bureau's and armies' experts. Information of the greatest importance to the war-making powers was obtained.

Early in February, 1917, when war between the United States and the Central Powers seemed inevitable, the bureau offered its services in the study of poisonous gases and gas-masks to the War Department, which was accepted. This was the beginning of the great organization of 1,700 chemists who constituted the Chemical Warfare Service at the American University at Washington and whose jurisdiction was afterwards turned over to the War Department. The bureau claims that as a result of its work, the United States was months ahead of where it otherwise would have been and the soldiers all had gas-masks of such quality that the War Department some time ago issued a statement to the effect that the gassing of a soldier was to be considered in the future as a matter of ignorance. Still further it is claimed by the bureau that through the energy of its research organization, the large-scale production of toxic gases was far ahead of the supply of shells.

Through its investigation of natural gases the bureau with the co-operation of the Army and Navy conducted important work relating to balloon gases. This work included the development of certain products for use in balloons that can be obtained from natural gas. No more can be said about this work at this time.

It was soon found that there would be a tremendous demand by the military authorities for the so-called war minerals. With the havoc wrought by the submarines, the world was short of shipping and the United States was informed that these minerals should come from American mines, many of which were either inadequately developed or not developed at all.

New Du Pont Company Formed

The Dupont Chemical Company has been incorporated at Wilmington, Delaware, with a capital of \$3,600,000 to manufacture chemicals, dyestuffs, etc. The directors are Hunter Grubb, C. R. Mudge and W. S. Thomas, all of Wilmington, Delaware.

It is announced from Wilmington that while the company is authorized to manufacture dyestuffs, its immediate purpose is to take over munitions machinery belonging to the E. I. Dupont de Nemours Company with a view to its ultimate use in other lines of industry. The incorporators are all connected with the Dupont powder interests.

The Evans-Thwing Company, of Fort Worth, Texas, has purchased a tract of land at Hodges Station, Texas, and will in the near future commence the erection of an oil refinery having a daily capacity of 3,500 barrels. The plant will be built upon the unit system. The first unit to be constructed will cost \$600,000.

German Industrial Position

Transfer of Alsace-Lorraine Blow at Nation's Industrial Strength

THE unanimity evident among the Allies regarding the return of Alsace-Lorraine to France, a unanimity which will inevitably result in a transfer of the "lost provinces" and all their immensely valuable natural resources to Allied control, should put an end effectually to any discussion of the possibility of Germany ever again obtaining the strangle-hold on certain chemical industries she possessed before war with the Allies broke out.

Alsace-Lorraine is not only one of the most highly developed manufacturing parts of the German Empire, but it is also one of Germany's chief sources of highly important raw materials. Industries, no matter how shaken they may be by the course of political events, may be reorganized and placed to a great extent on their former footing, but once a nation is deprived of a source of raw materials, such as Alsace-Lorraine, the loss is irremediable.

According to Dr. Felix Pinner, the financial editor of the Berliner Taglebatt, Alsace produced prior to the war 42 per cent of the crude oil produced in the German Empire. Further it contains potash deposits similar in composition to the famous Straasfurt deposits in central Prussia sufficient to assure those who control them freedom from any danger of ever again being placed in the power of the owners of the Prussian deposits. The loss of the Alsatian deposits will unquestionably put an end to the pre-war swashbuckling policy of the German potash barons and force them to either cut prices or make agreements with the owners of the Alsatian deposits.

The greatest blow to German industry and its ability to compete with other industrial nations in the markets of the world, will be dealt through the transfer of the Lorraine iron deposits. The amazing development of the German iron and steel industry since 1871 has been due to the possession of Lorraine. The entire iron and steel industry of Western Germany depended to a great extent upon the Lorraine mines. The Lorraine and Luxemburg mines supplied in 1913, 28,500,000 tons of iron ore out of a total of 35,000,000 tons for the whole of Germany. The loss of the Lorraine deposits will, therefore, mean that Germany will have to depend for her ore supply to a great extent on sources beyond her own boundaries.

EXPLOSIVE FIRMS TO UNITE

Circular Issued by Nobel's Gives Details of Amalgamation in Full

LONDON.—In a letter to its shareholders, Nobel's Explosive Company, Glasgow, gives details of the organization which will eventually link up many of the leading explosive firms and corporations of Great Britain, in an organization with an authorized capital of eighteen million pounds sterling. It is proposed to call the new corporation "Explosive Trades, Limited."

In summing up the statement adds:

"Your (Nobel's) directors are convinced that the closer co-operation to result from the adoption of this scheme is necessary to enable the explosives and allied trades to effectively deal with post-war problems. Such an amalgamation as is proposed will enable the various technical, commercial and financial problems to be more satisfactorily handled, and essential improvements in working conditions, and economies in manufacture and distribution to be introduced, so that the products of the company may be obtained by the consumers on such conditions as will enable the company, their employes and their customers to benefit by this amalgamation.

It is the opinion of W. D. Huntingdon, vice-president of the Davison Chemical Company, one of the largest producers of sulphuric acid in the United States, that conditions in the acid industry will not be seriously affected by the discontinuance of price fixing with the close of the present month.

In an interview given in Washington, Mr. Huntingdon said that for the first quarter of 1919 the prices would be identically the same as those fixed by the War Industries Board for the last quarter of 1918. These prices, he said, would undoubtedly be continued, until such time as there was a reduction in the cost of materials and cost of production.

Mr. Huntingdon further said that all acid produced in Southern plants outside that produced by the Government had been absorbed by the fertilizer industry, which during the year past had not been able to obtain an adequate supply.

It is the desire of the American Committee of the Ramsay Memorial Fund to make the fund an expression of the esteem for Sir William Ramsay in this country. Many have expressed a wish to contribute, but have held back on account of their inability to send in a sum commensurate with their esteem. This has been due to the numerous calls made upon all for the past two years. Small sums, from one to five dollars, will be welcomed by the committee, which is anxious to make the expression of appreciation as widespread as possible. Contributions may be sent to Prof. Charles Baskerville, chairman, College of the City of New York, or Mr. W. J. Matheson, treasurer, 21 Burling Slip, New York City.

NEW PUBLICATIONS

SUBSTITUTION OF NITRE CAKE FOR SULPHURIC ACID IN PICKLING STEEL.

E. E. Corbett, Chemical Engineer, Bureau of Mines, Department of the Interior, Washington, D. C.

While the investigation which resulted in the publication of this paper was undertaken primarily for the purpose of finding a means of conserving sulphuric acid, a commodity at that time very much needed in the manufacture of war materials, has at first sight been made unnecessary by the coming of peace, the thoroughness with which the author has investigated the question of the pickling of steel, will make his paper interesting and useful to chemists allied with the steel industry.

NOTES ON LIGNITE—ITS CHARACTERISTICS AND UTILIZATION.

S. M. Darling, Bureau of Mines, Department of Interior, Washington, D. C.

Designed to be read in conjunction with Bureau of Mines bulletin No. 89, "Economic Methods of Utilizing Western Lignites," and the report on "The Carbonizing and Briquetting of Lignite," issued by the Province of Saskatchewan, Canada, this publication of the Bureau of Mines with the aid of these other publications gives a comprehensive review of all information at present available in regard to the location and nature of the various lignites available in the United States and Canada.

There are, according to the author, 1,051,290,000,000 tons of lignite available in the United States, the greater part of it located in parts of the country that lack other adequate fuel resources. An effective use of the lignite resources of the country would not only, therefore, place at the disposal of these lignite districts an adequate fuel supply but would eliminate a great deal of wasteful transportation of coal over long distances, thereby relieving strain on the railroad systems and mines of the country at certain seasons of the year.

The author of this paper does not advocate the use of lignite in its raw state, this he rightly points out is impossible to any great extent, owing to the high percentage of moisture in the material and the difficulty experienced in handling it.

Instead of trying to burn the raw lignite, it may be used in a number of forms: (1) as dried lignite, the material being handled mechanically; (2) powdered fuel in cement kilns, railroad locomotives and other furnaces; (3) dried lignite briquets; (4) carbonized lignite, for use in suction power gas producers; (5) carbonized lignite briquets for domestic service in house heating stoves, and furnaces, fireplaces and cooking ranges. This latter fuel compares favorably according to the author with anthracite coal; (6) sulphate of ammonia and producer gas. The raw lignite when used in by-product gas producers of the Mond type, make sulphate of ammonia, produces gas and some tars of undetermined value.

NEW BAUMÉ SCALE FOR SUGAR SOLUTIONS

Bureau of Standards, Department of Commerce,
Washington, D. C.

Many different Baumé scales have been proposed and used in the past. At the present time there are still in use in the United States three different scales for liquids heavier than water. Two of these, namely, the "Holland" scale and the "Gerlach" scale are used in sugar work. Neither is adapted to modern requirements. The new table lies between the "Holland" and "Gerlach" scales and has three important advantages which should commend it for general use. They are: 1. It is based upon the specific gravity values of Plato which are considered the most reliable of any available. 2. It is based on 20°C, the most convenient and widely accepted temperature for sugar work. 3. It is based on the modulus 145, which has already been adopted by the Manufacturing Chemists Association of the United States, by the Bureau of Standards and by all American manufacturers of hydrometers.

This paper is now ready for distribution and those interested may obtain a free copy by addressing a request to the Bureau.

PAPERS AND ADDRESSES—Technical Association of the Pulp and Paper Industry—New York—64 pp.—$1.00.

This publication is a compilation of the papers and addresses delivered at the annual meeting of the Technical Association of the Pulp and Paper Industry held in New York City, in February last. While most of the papers have been published this collection should prove a valuable addition to the reference library of any chemical engineer. Copies may be obtained from the Secretary of the Association.

COLLOIDS AND FLOTATION—Frederick G. Moses—United States Bureau of Mines—Washington, D. C.—24 pp.

This paper is an attempt to point a way towards the elimination of certain troubles hitherto unexplained, experienced in the operation of flotation plants. These problems are considered in the light of certain facts of colloidal chemistry and physics.

After an exhaustive discussion of the usual difficulties encountered due to the presence of colloids, the writer comes to the conclusion that colloids interfere greatly with flotation and that in order to overcome this difficulty their removal is necessary. He points out that there are various ways of removing irreversible colloids, principal among which he mentions heating of the ore.

PAPER, PAPER PRODUCTS AND PRINTING MACHINERY IN PERU, BOLIVIA AND ECUADOR—Robert S. Barrett—Department of Commerce—Government Printing Office—10 cents.

Government experts are not inclined to be over sanguine in regard to the new gasoline substitute, recently announced from Washington. The "Liberty Fuel," which is based upon kerosene, is being subjected to further tests and it is likely that an official announcement will be made shortly by responsible officials.

According to Dr. Sidney B. Haskell, business manager of the Soil Improvement Committee of the National Fertilizer Association, the production of the potash lakes of Nebraska is steadily increasing. Potash actually in storage on October 30 last amounted to 40,000 tons. The actual total production during 1918 will be between 30,000 and 32,000 tons. During 1919 it will likely be about 40,000 tons.

A great deal of damage was done at the plant of the American Aniline Products Company, 66-68 University Place, New York City, by the explosion of a drum containing alizarine dye.

A meeting of the Chicago section of the American Chemical Society was held at the Chicago City Club of December 13. The program consisted of a report on the present employment of women chemists.

ANY SIZE OR SPECIFICATION
Three factories, situated in the East, Middle West and Pacific Coast, enable us to give you special service in the manufacture of tanks.
We have on hand reserve supplies of air-dried woods suited for the different chemical requirements, making prompt shipments possible.
Our many years' experience in handling tanks to standard and special specifications should be of value to you. Your specifications will have our immediate and careful attention.
